Glossary

Motif A discrete structural element (a mixture of α -helices, β -strands and/or loop) of a protein with a specialized function, such as interacting with DNA. For example, the helix-turn-helix motifs of $\gamma\delta$ -resolvase position one helix so that it can optimally insert into the major groove of the target DNA.

Sequence specificity Interactions that are dependent upon the protein recognizing, and forming contacts with, a sequence-specific pattern of donor and acceptor substituents within the DNA major and minor grooves. DNA-binding proteins generally display many levels of specificity, taking advantage of the overall shape of the DNA grooves as well as the nucleotide sequence.

Introduction

A protein's ability to recognize a specific deoxyribonucleic acid (DNA) sequence is essential for many biological processes, including initiation of replication and transcription and regulation of gene expression and development. Understanding the principles that govern these recognition events is therefore very important. In general, proteins that bind DNA use structural motifs that provide complementarity to the unique shape and electrostatic properties of the DNA double helix. Specificity arises partly through recognition of the pattern of functional groups presented by nucleotide bases in the DNA helix and partly through recognition of changes in helical structure caused by a given sequence. Although the number of specific protein–DNA interactions formed in a typical cell is immense, there are a relatively small number of structural motifs that are used by DNA-binding proteins. Proteins accomplish DNA recognition through a set of recurring structural themes that have been individually fine-tuned by evolution to bind to specific sequences. A number of DNA-binding proteins contain multiple repeats of these motifs, greatly increasing the binding affinity and specificity that can be achieved. This article summarizes the structural and chemical properties of proteins and DNA that contribute to sequence-specific recognition.

DNA Structure and Properties

The structural and chemical properties of DNA play an important role in defining protein–DNA interactions. The canonical DNA fold is that of a double-stranded helix with a core of stacked base pairs sandwiched between two highly electronegative phosphodiester backbone chains (**Figure 1(a)**). DNA base stacking and hydrogen bonding twist the helix, creating wide major (M) and narrow minor (m) grooves that form a repeating pattern parallel to the sugar-phosphate backbone (**Figure 1(a)**).

Major and Minor Grooves

The major groove is the primary site of sequence-specific protein–DNA interactions. The width of the major groove (~ 12 Å) matches well with the width of a protein α -helix, allowing for a highly complementary fit between the two elements. In addition, the major groove is rich in accessible polar and nonpolar groups presented along the base pair edges (**Figure 1**). These groups provide an important docking surface for protein recognition and binding. While the major and minor grooves of DNA share a similar depth, the minor groove is more narrow (~ 6 Å). Because of this difference, some distortion of the minor groove structure is usually necessary to accommodate the docking and insertion of protein structural elements. Although the DNA minor groove also contains functional groups that provide an interaction surface for proteins, there is less information about the actual sequence than is found in the major groove. As shown in **Figure 1(b)**, for example, C and T bases appear identical in the minor groove but can be distinguished in the major groove.

Unique Properties of DNA Bases

Unique DNA sequences are defined by the pairing of four nucleic acid bases: adenine (A), thymine (T), guanine (G), and cytosine (C). A–T base pairs are coordinated by two hydrogen bonds, while G–C base pairs are linked by three hydrogen bonds (**Figure 1(b)**). The additional hydrogen bond in a G–C base-pair leads to increased rigidity and thermal stability relative to the A–T base pair. DNA helices rich in A and T are therefore more flexible and melt at lower temperatures than those rich in G and C, allowing for sequence-dependent differences in malleability of the DNA structure upon protein binding.

The bulk of DNA-sequence recognition is due to interactions between protein side chains and functional groups on the base-pair edges in the major groove. Most of these interactions are through hydrogen bonds, but proteins often make hydrophobic contacts to the methyl group of thymine as well. The

Figure 1 Structural and chemical properties of DNA. (a) DNA exists as a double-stranded helix with a core of stacked base pairs sandwiched between a negatively charged deoxyribose-phosphate backbone. Atomic and space-filling representations are shown. The DNA major (M) and minor (m) grooves are labeled. Atoms are colored by element. (b) Watson-Crick base pairing in DNA. The major and minor grooves contain hydrogen-bond donors (blue), hydrogen bond acceptors (red), and hydrophobic groups (green) that can be recognized by DNA-binding proteins.

edges of guanine and cytosine present an asymmetric pattern of four hydrogen-bond acceptor and two hydrogen-bond donor groups, enabling easy discrimination of G-C versus C-G base pairs (Figure 1(b)). Lysine and arginine side chains are often found interacting with G-C base pairs in the major groove, generally by hydrogen bonding to the N and/or O atoms of G. The positions of hydrogen bond donors and acceptors along the edges of A-T and T-A base pairs in the major groove are symmetric, making discrimination more difficult (Figure 1(b)). However, A-T and T-A base-pairs can be readily distinguished by the bulky methyl group of thymine, which forms van der Waals contacts with a number of protein side chains. Side chains of glutamine and asparagine are often used to hydrogen bond to adenine in A-T base pairs of DNA.

Nonspecific Protein-DNA Interactions

Not all DNA-binding proteins recognize and directly contact a specific sequence. Some proteins instead depend only on recognition of the general shape and properties of the DNA helix for binding. An important component of such nonspecific

interfaces involves hydrogen-bonding interactions between the protein and the phosphates in the DNA backbone. These generally involve hydrogen bond donors such as the side chains of serine, threonine, tyrosine, asparagine, glutamine, and histidine, and the amide NH groups on the polypeptide backbone. A particularly common type of polar interaction involves the strongly electrostatic hydrogen bonds formed between positively charged lysine and arginine side chains and the negatively charged phosphates.

In addition to polar interactions with the phosphates, DNA-binding proteins also make numerous van der Waals contacts to the deoxyribose groups in the DNA backbone. The deoxyribose groups are primarily hydrophobic, lining the walls of the major and minor grooves of the helix (colored gray in Figure 1(a)). Analyses of high-resolution structures of a number of protein-DNA complexes have revealed that these are the most abundant types of interactions.

Specific protein-DNA interfaces generally contain similar types of polar phosphate interactions and abundant van der Waals contacts to deoxyribose groups that are found in non-specific interfaces. However, proteins that recognize specific DNA sequences also contain additional elements responsible for recognizing correct target sequences and for rejecting incorrect sequences. The nature of these structural motifs is described in the next section.

Protein Structural Elements Used to Bind DNA

α -Helices

The α -helix is the structural element most frequently used for sequence-specific interactions in protein-DNA interfaces. The size of an α -helix matches the width of the DNA major groove, allowing them to fit together tightly while the protein side chains on the helix probe the available base-pair functional groups. The mode of helix docking to the DNA varies widely among different DNA-binding domains that use this element. The maximum number of side-chain-DNA contacts can be achieved when the α -helix docks in the major groove with its axis parallel to the phosphate backbone. However, helices also insert into the major groove in an end-on fashion and with their helical axes parallel to the base pairs. Some examples can be seen in Figures 2(a)–2(d). Helices can insert into the DNA minor groove as well, as seen with the lactose repressor. However, because the minor groove must be distorted to fit the helix, this type of interaction is not often seen and generally only one or two residues from the helix are inserted.

β -Strands

β -Strands paired together to form small β -sheets are also found in sequence-specific DNA interfaces. In these complexes, the β -sheets lie flat within the major groove, where side chains on the exposed surface of the sheet interact with functional groups on the edges of neighboring base pairs. An example is the Arc repressor-DNA complex, shown in Figure 2(e). Larger β -sheets take on a rigid, slightly twisted structure and their insertion into either the major or minor groove requires considerable

Figure 2 Examples of DNA-binding motifs bound to specific DNA sequences: (a) helix–turn–helix, (b) basic leucine zipper, (c) basic helix–loop–helix, (d) zinc finger, (e) ribbon–helix–helix, and (f) β -sheet motifs bound to DNA. α -Helices and β -strands that form sequence-specific interactions with the DNA are colored red. Protein structural elements that form nonspecific contacts with the DNA phosphate backbone are colored yellow. Intercalating phenylalanine residues positioned along the TATA-box binding protein's β -sheet edge are colored green. The DNA is shown as a ribbon structure with the sugar-phosphate backbone colored orange and base pairs colored by atom. The Protein Data Bank codes for the examples are given in parentheses.

distortion of the DNA helix, as shown for the TATA-box binding protein (TBP) in [Figure 2\(f\)](#).

Loops

Both α -helices and β -strands act as rigid scaffolds that direct residue side chains into the DNA major groove in a specific orientation. In contrast, protein loops have the versatility to adopt a wide range of conformations. This flexibility allows the loop to vary its position within the DNA major groove, altering the orientation of specific residues in order to achieve optimal side chain–base interactions. Loops are common DNA-binding elements in DNA-binding proteins with immunoglobulin-like domains, such as the tumor suppressor p53 and the transcription factor nuclear factor-kappaB (NF- κ B).

DNA-Binding Motifs

There are currently over 1500 high-resolution structures of protein–DNA complexes deposited in the Protein Data Bank,

representing approximately 10 different DNA-binding motifs. The motifs contain a mixture of α -helical, β -strand, and loop structural elements that interact via the DNA major and minor grooves. Summarized below are examples of the most common DNA-binding motifs. More in-depth descriptions can be found in the texts recommended for further reading.

Helix–Turn–Helix

The helix–turn–helix (HTH) motif consists of a right-handed three helical bundle with helices $\alpha 2$ and $\alpha 3$ arranged perpendicular to one another ([Figure 2\(a\)](#)). Sequence-specific DNA binding is mediated by the recognition helix $\alpha 3$, which docks into the DNA major groove forming hydrogen-bond and van der Waals contacts with functional groups on the exposed base pairs and the deoxyribose-phosphate backbone. The protein–DNA interaction is stabilized by nonspecific contacts between the DNA backbone and residues in $\alpha 2$ and the turn between $\alpha 2$ and $\alpha 3$. HTH motifs often exist as parts of larger domains and the orientation of $\alpha 3$ within the major groove is greatly dependent on the tertiary structure of the surrounding

elements. In prokaryotic DNA-binding proteins, HTH motifs function as homodimers with $\alpha 3$ docking parallel to the base-pairing edges within the major groove. In contrast, $\alpha 3$ from monomeric eukaryotic HTH motifs binds parallel to the DNA sugar-phosphate backbone and tracks along the major groove. The HTH–DNA interaction is elaborated in some DNA-binding domains by the insertion of additional motifs that provide auxiliary contacts to the DNA helix. For example, the winged HTH motif involves the combination of the HTH motif with a flanking β -hairpin that extends the protein–DNA interface.

Basic Leucine Zipper and Helix–Loop–Helix

Leucine zippers (bZIP) are rigid dimers of parallel extended helices. The dimer is stabilized by a coiled-coil interaction between heptad repeats of hydrophobic leucine and/or isoleucine residues along the C-terminal regions of each helix. A well-studied example is the DNA-binding domain from the transcription factor GCN4 shown in [Figure 2\(b\)](#). The two N-terminal regions in the bZIP domain splay out from the coiled coil and straddle the DNA major groove. Interestingly, the bZIP N-terminal DNA-binding regions are often unstructured in the absence of DNA. This lack of structure presumably allows the protein to sample a variety of potential interactions within the exposed DNA elements until the optimal DNA target sequence is found. Side chains on the docked helices form specific contacts with the target nucleotides and nonspecific contacts with the surrounding sugar-phosphate backbone. Coupling helical structure formation to DNA binding and sequence recognition is an interesting example of how specificity can be regulated in a DNA-binding protein.

Basic helix–loop–helix (bHLH) motifs are modifications of the extended helical structure of bZIP proteins. The bHLH monomeric unit consists of two short extended helices – a C-terminal coiled-coil dimerization helix and an N-terminal DNA-binding helix – separated by a loop. An example is shown in [Figure 2\(c\)](#). Dimerization results in the formation of a four-helix bundle near the loop, allowing for increased flexibility in the positioning of the N-terminal helices in the DNA major groove. Both the bZIP and bHLH motifs can exist as homo- and heterodimers, greatly increasing the variety of target DNA sequences recognized by these proteins.

Zinc Finger

Zinc fingers are encoded by approximately 3% of the human proteome and are the most common DNA-binding motif in eukaryotes. Transcription factors often use zinc fingers to mediate protein–DNA interactions. The most common zinc finger motif consists of a two-stranded anti-parallel β -sheet and a short α -helix ($\beta\beta\alpha$) held together by a Zn^{2+} ion tetrahedrally coordinated by conserved cysteine and histidine residues in the α -helix and two β -strands ([Figure 2\(d\)](#)). In all cases, Zn^{2+} plays a structural role and does not interact directly with the DNA. The α -helix serves as the recognition element, inserting into the DNA major groove where side chains form specific contacts with three consecutive base pairs. The overall interaction is further stabilized by nonspecific contacts between the β -sheet and the sugar-phosphate backbone of DNA.

Zinc fingers generally occur in units of 3–15 tandem repeats, where the number of DNA-binding motifs directly affects the sequence specificity of the interaction. The length of the linker region between zinc fingers determines the number and spacing of the recognition helices docked in the DNA major groove. It is also common for the linker regions and zinc fingers to form stabilizing nonspecific contacts across the DNA minor groove. The use of multiple zinc finger motifs in a single DNA-binding module allows for recognition of an extended (and therefore more specific) DNA sequence, since each finger can in principle recognize a base-pair triplet. This modular feature has also led to the development of engineered zinc finger DNA-binding proteins that can be tailored to bind specifically to alternative sequences of interest.

β -Ribbon–Helix–Helix

The ribbon–helix–helix motif consists of two intertwining monomers, each of which contains a β -strand followed by two α -helices ($\beta\alpha\alpha$)₂ ([Figure 2\(e\)](#)). Dimerization generates a two-stranded anti-parallel β -sheet, which is the primary DNA-binding element. Initial contacts between the sugar-phosphate backbone and the $\alpha 2$ peptide backbone play a critical role in orienting the β -sheet for insertion into the DNA major groove with the strands parallel to the sugar-phosphate backbone. Once docked, side chains on the exposed face of the sheet form hydrogen bonds with functional groups on the base-pair edges. The complex is stabilized through additional contacts between the helices and the sugar-phosphate backbone. The ($\beta\alpha\alpha$)₂ motif often dimerizes to form a symmetric tetramer that can recognize both symmetric and asymmetric DNA sequences, as shown in the example in [Figure 2\(e\)](#). The specificity and stability of ($\beta\alpha\alpha$)₂–DNA interactions can be further enhanced by the insertion of additional structural elements into the minimal ribbon–helix–helix fold.

β -Sheet

The TBP represents one of the few protein families that use an extended β -sheet to bind target DNA. TBP is a transcription factor that recognizes and binds to a TATA-box sequence that is extremely A/T-rich. TBP consists of two domains separated by a concave anti-parallel 10-stranded β -sheet which covers and binds at the DNA minor-groove (shown in [Figure 2\(f\)](#)). This interaction is facilitated by two phenylalanine residues from each β -sheet edge which intercalate into the DNA minor groove. This intercalation causes a broad opening of the minor groove and large-scale distortion of the DNA which can then accommodate the twisted structure of the large sheet. Sequence specificity is achieved through contacts between residues on the β -sheet surface and the edges of newly accessible base pairs and through the sequence-dependent deformability of the A/T-rich TATA-box sequence.

Conclusions

Proteins have evolved a number of structural motifs capable of binding to specific DNA sequences. Complementarity of the protein motifs with the shape and properties of the DNA double helix governs initial protein–DNA docking and

provides a substantial fraction of binding affinity. Specificity is achieved primarily through side-chain interactions with patterns of polar and nonpolar groups presented along the base-pair edges of a target DNA sequence within the major and minor grooves. Sequence-dependent deformations of the DNA helix also contribute to binding specificity. Proteins mediating tightly regulated processes often employ a combination of motifs to ensure a high level of specificity and affinity for the correct sequence. Understanding the factors that govern specific protein–DNA interactions has important implications in the identification of regulatory sites in genomes, as well as in the *de novo* design and engineering of DNA-binding proteins with altered affinities and/or specificities.

DNA Supercoiling

T-S Hsieh, Duke University Medical Center, Durham, NC, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

DNA twist The number of times that two complementary strands wind around one another in the double-helical structure.

Kilobase (kb) One thousand base pairs.

Linking number The number of times that DNA strands wind around one another in space. For a closed circular DNA, it is an integer and an invariant.

Supercoil The winding of the DNA helical axis in space.

Topoisomerase An enzyme that can change supercoiling or other aspects in the topological structure without altering any covalent structure in DNA.

Background

The beauty and elegance of the double-helical structure of DNA, as first proposed by Watson and Crick in 1953, also impart critical functions of DNA. However, the unwinding and rewinding of the DNA double helix during the process of replication, transcription, and recombination create intriguing topological problems. The potential topological problem intrinsic to a circular, double-stranded DNA molecule was first noted by Cairns in 1963. In his autoradiographic analysis of chromosome replication in the bacterium *Escherichia coli*, Cairns pointed out that the bihelical DNA structure of a circular molecule poses a topological constraint on the strand separation necessary in the process of DNA replication. About the same time, Vinograd and his associates demonstrated that an animal virus, polyomavirus, also has a circular genome. Furthermore, the helical axis itself winds and turns in space, thus producing a superhelix. Since then, circular genomes have been discovered in many organisms, including most bacteria, bacterial plasmids, and organelles such as mitochondria and chloroplasts. For example, Figure 1 shows an electron micrograph of a small bacterial plasmid DNA. The DNA superhelicity results in a duplex making crossovers (intersections) with itself. For most circular DNAs isolated from natural sources, the number of superhelical turns is directly proportional to the length of DNA. There are approximately six to eight superhelical turns per 1 kb DNA. We discuss the quantitative details in later sections.

The biological significance of DNA superhelicity was first realized when Vinograd and his co-workers discovered that there is a tight coupling between the DNA secondary structure and superhelical structure. Therefore, DNA superhelicity can influence the unwinding and rewinding of DNA duplex, and vice versa. Because such a coupling is direct, it allows one a rare opportunity in molecular biology to design experiments to gain insight into the structure of DNA and to probe the mechanism of the enzymes that affect DNA structure. The theoretical consideration of the coupling between DNA secondary and tertiary structures, based on mathematical topology, was later extended in the treatises by Fuller, White, and Crick. It should be pointed out that such a topological coupling also applies to linear DNA with anchored sites to create the loop structure that is found in the chromosomes of essentially all cells.

Nature has evolved unique enzymes to solve the topological problems that arise during the process of unwinding/rewinding DNA helix. The first such enzyme, topoisomerase I from the bacterium *E. coli*, discovered by Wang in 1970, can remove negative supercoils efficiently. Many new families of topoisomerases have since been discovered, and these enzymes are present in all organisms and have essential biological functions.

Quantitative Relationship between Twist and Supercoil

For a circular DNA without any nicks, in which both DNA strands are covalently continuous, the sum of DNA twists (Tw) and writhes of the DNA helical axis (Wr), a measure of DNA superhelical structure, is invariant. Because the algebraic sum of these two numbers is equal to the number of times that one of the DNA strands winds around its complementary strand in space, it defines the topological linkage between DNA strands, termed the linking number (Lk). We therefore have the following equation:

$$Tw + Wr = Lk$$

where Lk is a constant for a covalently closed circular DNA. Tw is related to the DNA secondary structure, the bihelical winding of two DNA strands, and it can be calculated if one knows the size of the DNA and the average helical pitch in this DNA. For example, in a 1-kb B-form DNA with a helical pitch of 10.5 bp/turn, $Tw = 95$. Wr is a measure of the superhelical structure of DNA. It relates to the number of times that the helical axis crosses itself in space. The higher the Wr , the more supertwisted the DNA. Lk is a topological quantity and defines the total linkage between the two complementary strands. Whereas Tw and Wr can be any real number, Lk is always an integer. This is because, for a closed circular DNA, strands have to wind around one another an integral number of turns to avoid nicks or gaps.

Handedness and the Sign of Tw and Wr

An important feature for all three parameters is that each has a sign, positive or negative, depending on the handedness of

the double helix and superhelix. Because most of the DNA duplexes are right handed, we define right handed as positive and left handed as negative. We can define whether the cross-over of two curves in space is left handed or right handed if an axis is clearly marked. For example, **Figure 2** shows two curves, denoted as two arrows in space, one making a left-handed cross (**Figure 2(a)**) and the other a right-handed one (**Figure 2(b)**). The axis is shown as a thin vertical line going through the crossover. The significance of the definition of the axis can be

Figure 1 An electron micrograph of a bacterial plasmid DNA. The DNA has about three superhelical turns, as evidenced by the number of crossovers made by the DNA duplex.

Figure 2 Diagrams of (a) a left-handed crossover and (b) a right-handed one. The arrows shown here serve to illustrate the point that the two perpendicular axes, one vertical (shown here) and one horizontal, are not equivalent. They also illustrate the rotational process to bring upper strand to the lower one. The directionality of such rotation is marked with a curved arrow around the helical axis.

visualized in this figure as well. If one chose instead a horizontal line as the axis, then the assignment of handedness is reversed. **Figure 2(b)** would then be left handed and **Figure 2(a)** would be right handed. For the duplex DNA structure, the axis definition is rather intuitive and straightforward. The helical axis is the axis around which the two strands are wrapped with respect to one another. There is an alternative method in defining handedness without the concern of marking a helical axis. It is based on the relative rotation of upper strand to the lower one (red arrow over blue in **Figure 2**). If a counterclockwise rotation is required to make the upper strand coincident with the lower one, then it is right handed; conversely, a clockwise rotation for upper strand matching the lower one will be defined as left handed.

For the DNA superhelix, it is easier to use the upper-to-lower strand rotation to define handedness. However, it is also possible to mark the helical axis for handedness definition. In this case, it is necessary to define an axis in a manner that is consistent with what we defined for secondary structure. An example is shown in **Figure 3**. A superhelical DNA with two superhelical turns is shown here. If one lays down the superhelical DNA horizontally, then the axis is the vertical line going through the crossover. With this definition of axis, the superhelix shown in **Figure 3(a)** has two left-handed crossovers, and thus it has two negative superhelical turns ($Wr = -2$); **Figure 3(b)** has two positive superhelical turns ($Wr = +2$).

Because it is not practical to measure the absolute value of Wr or Lk , they are usually determined experimentally with respect to a reference state, DNA in a relaxed state. The linking number and writhe for the relaxed state are denoted with a subscript zero.

Because $Wr_0 = 0$, the measure of DNA supercoils, Wr , is equal to the writhe difference with respect to the reference state:

$$Wr = \Delta Wr = Wr - Wr_0$$

Assuming that Tw for the supercoiled and relaxed DNA is about the same ($Tw = Tw_0$), then it follows that

$$\Delta Wr = \Delta Lk$$

Figure 3 Diagram of a superhelical DNA with (a) two left-handed supercoils and (b) with two right-handed supercoils. Notice the two complementary strands (in red and blue) are wound in a right-handed helix. The axis for determining the handedness of the superhelical turn is shown as a vertical line going through the DNA crossovers.

Because Lk is a topological invariant, it does not change for a given DNA in different environments. It is thus a more useful parameter for tracking the structure of DNA. As a result, ΔLk is frequently used to mark the superhelicity of DNA. If ΔLk is negative, DNA is underwound; the absolute value of ΔLk in this case gives a measure of negative supercoils or linking deficiency. If ΔLk is positive, then the DNA is overwound; its absolute value relates to the number of positive superhelical turns. DNA superhelicity can also be expressed as a fraction with respect to the linking number in a relaxed DNA. This is usually referred to as superhelical density, σ :

$$\sigma = \Delta Lk / Lk_0 = \Delta Lk / Tw_0$$

because $Lk_0 = Tw_0$, when $Wr_0 = 0$.

Most of the circular DNAs isolated from natural sources are negatively supercoiled. An interesting exception is the DNA in hyperthermophilic bacteria and archaeobacteria, which is usually positively supercoiled. For the numerous negatively supercoiled DNAs studied so far, the superhelicity mostly falls within a narrow range, with σ between -0.06 and -0.08 .

Biological Effects of Supercoiling and Enzymes That Can Change DNA Supercoiling

To access the genetic information embedded within the double helix, most of the biological processes associated with critical functions of DNA involve unwinding or rewinding of the twin DNA strands. With a covalently closed circular DNA for which Lk stays constant, any change in Tw will be compensated by a change in Wr that is equal in magnitude but opposite in sign:

$$\Delta Tw = -\Delta Wr$$

This quantitative coupling between the DNA secondary structure and superhelical structure suggests that supercoiling can profoundly influence DNA structure and function. DNA with supercoils, either positive or negative, is thermodynamically less stable than its relaxed counterpart. For a negatively supercoiled DNA, any reactions associated with a reduction in the negative superhelical turns ($\Delta Wr > 0$) are energetically favored. These reactions will also be coupled with the unwinding of the DNA duplex because $\Delta Tw < 0$ if $\Delta Wr > 0$. Therefore, negative DNA supercoiling facilitates the unwinding of DNA. In many instances, it has been demonstrated that replication, transcription, and recombination, all of which require the

unwinding of DNA, are promoted by negative supercoiling. In an interesting corollary, DNA with positive supercoils will favor winding and disfavor unwinding of duplex structure (i.e., $\Delta Tw > 0$ if $\Delta Wr < 0$). It has been hypothesized that positive supercoiling found in some of the hyperthermophiles serves to stabilize the DNA double-helical structure in the extreme temperatures at which these organisms find home.

Nature has harnessed the use of DNA supercoiling for regulating the biological functions of DNA; it has also developed tools to modulate supercoiling. A ubiquitous class of enzymes, DNA topoisomerases, evolved to carry out the topological transformation in DNA. In order to break the hold of the topological constraint on closed circular DNA, these enzymes can make transient and reversible DNA breaks. There are two important features in these topoisomerase-mediated breaks in comparison with those made by nucleases. One is that a specific tyrosyl residue in the enzyme is joined covalently to the phosphate at the breakage site through a phosphodiester bond. Because this enzyme–DNA bridging bond is made at the expense of the neighboring DNA backbone bond, there is no significant energy change associated with the process of strand scission, thus assuring that the cleavage/religation is readily reversible. The enzyme-mediated DNA breakage is also accompanied by strand passage through the break or a rotation of the strand with the transient break around the intact strand. Both processes result in a change of DNA supercoiling or other topological transformation in DNA. Indeed, genetic experiments have demonstrated essential functions of these enzymes in the cell. These results also underscore the importance of supercoiling in the biological functions of DNA.

Glossary

Catenane Two interlocked circular DNA molecules in which the two duplexes are wound around each other one or more times.

Catenate The process whereby two circular DNAs are interlocked to form a catenane. The unlocking of catenated DNAs is referred to as decatenation.

Closed circular DNA Circular DNA in which both strands are intact.

DNA gyrase DNA topoisomerase that couples the hydrolysis of adenosine triphosphate (ATP) to the introduction of negative supercoils into a closed circular DNA.

DNA supercoiling The coiling of the axis of a DNA molecule in three-dimensional space. Supercoiling may result either from an interaction of the DNA with protein or from an inequality between the number of helical turns dictated by the structure of the DNA helix under a particular set of conditions (the twist of the DNA) and the linking number of the DNA.

Linking number Topological property of a closed circular DNA that is a measure of the fixed interwinding of the two DNA strands.

Precatenanes The interwinding of the two daughter duplexes behind a replication fork.

Reverse gyrase DNA topoisomerase that couples the hydrolysis of ATP to the introduction of positive supercoils into a closed circular DNA.

Scissile strand The strand of DNA that is cleaved by a type I topoisomerase.

Topoisomerase Enzyme that changes the linking number of a closed circular DNA by temporarily breaking one (type I) or both (type II) of the strands of the DNA.

Topoisomers Variants of a closed circular DNA that have different linking numbers.

Torsionally strained supercoils Supercoils that result from an inequality between the number of helical turns dictated by the structure of the DNA helix under a particular set of conditions and the linking number of the DNA.

Both the large size of DNA molecules and the double-helical nature of DNA create unique topological problems during replication, transcription, recombination, and chromatin remodeling, which are solved by a family of enzymes called DNA topoisomerases. Members of the type II subfamily of DNA topoisomerases alter the supercoiling of DNA and disentangle chromosomes by introducing temporary double-strand breaks into the DNA. Type I DNA topoisomerases, the subject of this article, manage DNA topology in the cell by transiently cleaving only one of the two DNA strands.

Reactions Catalyzed by Type I DNA Topoisomerases

To introduce a temporary single-strand break into duplex DNA, type I DNA topoisomerases must catalyze the cleavage and subsequent religation of a DNA strand. Since these two reactions occur without external energy sources such as adenosine triphosphate (ATP), cleavage cannot result from simple hydrolysis of a phosphodiester bond in the DNA. Instead, a covalent enzyme–DNA intermediate is generated that makes the religation step energetically feasible. The formation of the covalent intermediate involves nucleophilic attack by the O-4 atom of the active site tyrosine in the enzyme on a phosphodiester bond in the DNA to produce a phosphodiester bond between the tyrosine and the DNA and leave a free DNA hydroxyl end. DNA religation and release of the enzyme is the reverse reaction with the oxygen of the free DNA hydroxyl acting as the nucleophile. The type I enzymes display a loose preference for certain

nucleotides in the vicinity of a cleavage site; therefore, a cleavage site typically occurs every 5–20 base pairs along the DNA.

By introducing a transient nick in DNA, type I topoisomerases can act on closed circular DNAs to change the number of times one strand winds around the other, a parameter referred to as the linking number of the DNA. Changes in the linking number are reflected in either a reduction or an increase in the supercoiling of a plasmid DNA, a property that is most often measured by gel electrophoresis. In addition to altering the supercoiling of a plasmid DNA, many type I topoisomerases are capable of catalyzing a number of other transactions involving both single- and double-stranded DNAs. Most of these enzymes can catenate (interlock), decatenate, knot, and unknot single-stranded DNA circles. The same series of reactions can be carried out with duplex circular DNAs, provided at least one of the circular molecules possesses a nick or a gap. In some cases, the enzymes can facilitate the interwinding required for the renaturation of two complementary single-stranded circular DNAs, a reaction that could be important during homologous recombination. Interestingly, topoisomerase V, which has only been described in the hyperthermophilic archaeon *Methanopyrus kandleri*, possesses, in addition to the usual topoisomerase activity, an apurinic/apyrimidinic site-processing activity that would appear to implicate the enzyme in DNA repair. Finally, with certain unusual DNA substrates, a block to religation leads to permanent suicide cleavage and the enzyme remains covalently linked to the DNA. The anti-cancer drug camptothecin blocks religation and similarly leads to the accumulation of enzyme–DNA covalent complexes.

Classification, Nomenclature, and General Properties

Type I topoisomerases are classified into three distinct subfamilies (types IA, IB, and IC) based on structural considerations. In addition, the type IA subfamily differs from the IB and IC subfamilies with respect to which DNA end becomes covalently attached to the enzyme during the cleavage reaction: type IA enzymes attach via a tyrosine phosphodiester linkage to the 5' end of the DNA, whereas the enzymes in the other two subfamilies attach to the 3' end of the DNA. **Table 1** lists the known type I DNA topoisomerases in the three subfamilies with their common names and origins; representatives of the IA and IB topoisomerases are found in all three domains of life, while the only known member of the IC subfamily is found in an archaeon. The common names have generally been assigned in the order of discovery using odd Roman numerals (even Roman numerals are similarly used for type II DNA topoisomerases). Type I enzymes with unusual properties or origins have been given unique names (reverse gyrase, poxviral topoisomerase, and mitochondrial topoisomerase). The recently described IB enzymes in some eubacteria are referred to as bacterial topoisomerases IB.

The three categories of type IA enzymes listed in **Table 1** can be distinguished on the basis of the types of reactions they catalyze. Topoisomerases I relax negative but not positive supercoils in plasmid DNAs; however, since relaxation does not go to completion, some residual negative supercoils remain in the product. Topoisomerases III require hypernegatively supercoiled plasmid DNA as a substrate and again relaxation is incomplete. Interestingly, topoisomerases III are much more proficient than the topoisomerases I in DNA catenation and decatenation (see below). Reverse gyrases, which are only found in hyperthermophilic and some thermophilic eubacteria and archaeobacteria, introduce positive supercoils into plasmid DNAs at the expense of ATP hydrolysis. All of the type IA enzymes require Mg^{2+} and are monomeric with the exception of the reverse gyrase from the archaeon *M. kandleri* which is a heterodimer.

The type IB DNA topoisomerases are capable of relaxing both positive and negative supercoils in a reaction that does not require ATP or divalent cations. Although the reactions go to completion to produce a completely relaxed set of plasmid DNA topoisomers, the nuclear enzyme in eukaryotes exhibits a

preference for binding supercoiled DNAs of either sign over completely relaxed DNA. With the exception of the recently discovered heterodimeric topoisomerases I from trypanosomatids, all of the type IB enzymes are monomeric.

Type IA DNA Topoisomerases

Protein Domains

All type IA topoisomerases (**Table 1**) share a highly conserved cleavage/strand-passage domain that contains the active site tyrosine. This domain is also responsible for promoting the structural change in the DNA during the interval between the cleavage and religation reactions that results in a linking number change (see below) (**Figure 1**, red boxes). As indicated in **Figure 1**, all type IA enzymes contain a poorly conserved basic C-terminal domain (solid or hatched green boxes) and some contain a Zn(II)-binding domain as well (blue boxes). These latter two features appear to be important for the interaction of the enzyme with DNA. Finally, reverse gyrases contain an N-terminal domain, which resembles the ATPase domains of helicases (yellow box) and is connected to two domains that are structurally very similar to the cleavage/strand-passage and basic domains of the typical type IA topoisomerases.

Crystal Structure of the Conserved Cleavage/Strand-Passage Domain

The crystal structure of the cleavage/strand-passage domain of *Escherichia coli* DNA topoisomerase I shown in **Figure 2** provides key insights concerning the substrate preference of the enzyme and the mechanism of DNA relaxation. Notably, the cleavage/strand-passage domains of all type IA topoisomerases bear a strong resemblance to the *E. coli* structure. The hallmark of the crystal structure is a toroidal shape in which the diameter of the hole in the center of the torus is sufficient to accommodate either single- or double-stranded DNA.

The requirement for a negatively supercoiled substrate and the inability to completely relax negative supercoils is best explained by supposing that these enzymes will only bind an otherwise duplex DNA substrate if it contains a single-stranded region resulting from local unwinding of the helix. A plasmid

Table 1 Type I DNA topoisomerases

Subfamily	Common name	Source	Structure
IA	Topoisomerase I	All eubacteria and some archaeobacteria	Monomer
IA	Topoisomerase III	Some eubacteria and most eukaryotes	Monomer
IA	Reverse gyrase	All hyperthermophilic eubacteria and archaea	Monomer
IA	Reverse gyrase	Archaeon <i>Methanopyrus kandleri</i>	Heterodimer
IB	Topoisomerase I	Nucleus of all eukaryotes	Monomer
IB	Mitochondrial topoisomerase	Mitochondria of higher eukaryotes	Monomer
IB	Poxviral topoisomerase	All members of poxviridae family	Monomer
IB	Topoisomerase IB	Some eubacteria	Monomer
IB	Topoisomerase I	Archaea <i>Cenarchaeum symbiosum</i> and <i>Nitrosopumilus maritimus</i>	Monomer
IB	Topoisomerase I	Trypanosomatids <i>Trypanosoma brucei</i> and <i>Leishmania donovani</i>	Heterodimer
IC	Topoisomerase V	Archaeon <i>Methanopyrus kandleri</i>	Monomer

Figure 1 Domain structure and sequence relationships between type IA DNA topoisomerases. The domain structure of representative type IA topoisomerases is denoted by colored boxes. The names of the domains for the prototypic *E. coli* DNA topoisomerase I are given along the top. The cleavage/strand-passage domains shared by all the IA enzymes are shown in red. Green is used to denote the basic C-terminal domains, but the different types of fills for these boxes indicate that these domains are poorly conserved. Some type IA enzymes contain a Zn(II)-binding domain shown in blue. The helicase-like domain of reverse gyrase is shown in yellow.

Figure 2 A ribbon diagram showing the crystal structure of the cleavage/strand-passage domain of *E. coli* DNA topoisomerase I (pdb entry 1ec1) drawn with Swiss-Pdb Viewer software (Glaxo Wellcome Experimental Research). The approximate path of the bound single-stranded substrate DNA is indicated by the solid black line, and the active site tyrosine is shown in magenta. The two regions of the protein that move relative to each other (double-headed arrow) to open and close the torus during the strand-passage reaction and to release the DNA are shown in green and orange.

DNA that is highly negatively supercoiled is energetically disposed toward helix unwinding, which explains why such a DNA is a good substrate for the enzyme. However, relaxation ceases when the negative supercoiling falls to a level below which there is insufficient energy to promote the required opening of the helix. As shown in [Figure 2](#), a single strand of DNA (solid black line) binds to a narrow groove on the cleavage/strand-passage domain of the enzyme in close proximity to the active site tyrosine (magenta).

Enzyme-Bridging Mechanism for Strand Passage

To change the linking number of a closed circular DNA during relaxation, one strand of DNA must pass through a break in the

other strand. Knotting, catenation, and decatenation of either single- or double-stranded DNAs similarly require such a strand-passage event. The strand-passage reaction for type IA topoisomerases occurs by what is referred to as an enzyme-bridging mechanism. Once the scissile DNA strand is cleaved, both DNA ends remain tightly associated with the enzyme; the 5' end is bound covalently to the active site tyrosine and the 3' end is bound noncovalently to the enzyme. To orchestrate strand passage, the enzyme undergoes a conformational change in which the top half of the protein containing the 5' end of the cleaved strand ([Figure 2](#), shown in green) lifts upward to generate a gate in the DNA through which another strand of DNA is passed. After strand passage, the broken strand is religated and the enzyme opens up a second time to release the strand that had been passed into the hole of the torus. This model predicts that the linking number can only be changed in steps of one and this prediction has been verified biochemically.

This same scheme can explain how the enzyme can catenate or decatenate a DNA containing a nick or a gap. However, it is unclear whether the DNA that passes through the temporary gate in the cleaved strand is captured in the hole of the torus before strand cleavage and is then passed out of the hole after cleavage or vice versa as described previously.

Reverse Gyrase Mechanism

Despite the presence of a helicase-like ATPase domain in the N-terminal region of reverse gyrases, these enzymes lack helicase activity when assayed under conditions that would require processive translocation along the DNA, and the N-terminal domain alone does not unwind DNA. Instead, the binding of the N-terminal domain to DNA in the context of the complete enzyme is believed to unwind a region of a closed DNA that, in turn, produces positive supercoiling within a region elsewhere in the same molecule. Subsequently, in a reaction dependent on ATP, one of the two strands in the unwound region is cleaved and the other strand is passed through the resultant gate by the cleavage/strand-passage domain present in the C-terminal half of the molecule. ATP hydrolysis releases

the enzyme, leaving behind the positive supercoils. The key to positive supercoiling is that the strand-passage event that occurs in the presence of ATP is directional such that the linking number of the DNA is increased and therefore the DNA ends up positively supercoiled.

Type IB DNA Topoisomerases

Domain Structure and Sequence Conservation

Type IB DNA topoisomerases are present in the nucleus of all eukaryotic cells and the mitochondria of higher eukaryotes, as well as in some archaea and eubacteria (Table 1). The typical eukaryotic type IB enzyme possesses the four domains shown in Figure 3. A highly charged and poorly conserved N-terminal domain (red box) is followed by the core domain (blue box), which binds DNA and contains most of the catalytic residues. The active site tyrosine is found in the C-terminal domain (yellow box) that is connected to the remainder of the protein by a poorly conserved linker region (orange box).

All of the other type IB enzymes share at least partial sequence and structural homology with the catalytically important core domain, as can be seen from the color scheme in Figure 3 (blue boxes). Where present, the sequence of the mitochondrial enzyme is very similar to the nuclear enzyme with the exception of the N-terminal region (green box), which contains the organelle targeting signals. The archaeal-type IB topoisomerases lack the N-terminal domain, but are otherwise very similar to the eukaryotic enzymes. The eubacterial IB enzyme and the vaccinia topoisomerase are very similar to each other, but they lack most of the core domain as well as the conserved C-terminal domain that is characteristic of the other IB enzymes; instead, they share unique N-terminal and C-terminal regions (white and magenta boxes). The topoisomerase I found in the trypanosomatids is a heterodimer with one subunit containing the catalytic

core (blue box) and the other subunit containing a region homologous to the C-terminal domain of the prototypic eukaryotic sequence (yellow box).

Crystal Structure of Human Topoisomerase I

Two views of the crystal structure of human topoisomerase I (missing the N-terminal domain) with a bound 22-base-pair duplex oligonucleotide are shown in Figure 4. The protein is a bilobed structure that clamps completely around the DNA with the active site tyrosine (shown in black in Figure 4(a)) juxtaposed to the scissile phosphate. The linker region comprises the coiled-coil structure that protrudes conspicuously from the bottom portion of the enzyme and has an unknown function (Figure 4(a)). To release the DNA, the top half of the protein (shown in blue) must shift upward relative to the bottom half, as indicated in Figure 4(b) by the double-headed arrow. Likewise, DNA binding requires that the protein clamp be in an open conformation. The region of the human topoisomerase I structure shared by the poxviral and eubacterial IB enzymes corresponds to the portion of the core domain, depicted in yellow in Figure 4. Tyrosine recombinases, such as the bacteriophage λ and HP1 integrases, and cre recombinase are also structurally very similar to approximately the same region.

Catalysis

The co-crystal structure of human topoisomerase I with bound DNA reveals which amino acid residues in the protein are directly involved in catalysis. It is worth noting that the nucleophilic tyrosine O-4 does not appear to be activated for cleavage by general base catalysis, although a lysine residue acts as a general acid to protonate the leaving 5' oxygen. The pentavalent transition state is stabilized by hydrogen-bonding interactions between three basic amino acid side chains and the

Figure 3 Domain structure and sequence relationships between type IB topoisomerases. The domain structure of the type IB topoisomerases from the indicated sources are denoted by colored boxes with similar domains aligned vertically. The names of the domains for the eukaryotic type IB topoisomerases are shown along the top. Regions that are similar in amino acid sequence share the same color; distinct sequences are assigned different colors. The two subunits of the heterodimeric topoisomerase I from trypanosomatids are shown with these same color conventions.

Figure 4 The ribbon diagrams show two views of the crystal structure of human topoisomerase I clamped around a 22-base-pair duplex DNA, shown in gray (pdb entry 1a36). The top lobe of the enzyme is shown in blue and the bottom lobe is shown in red and yellow. The poxviral topoisomerase and the eubacterial topoisomerases IB are structurally very similar to the region of the bottom lobe, shown in yellow. The coiled-coil linker region in bottom lobe (in red) is most easily seen in the side view shown in (a). The active site tyrosine (in black) is shown in (a). Panel (b) shows a view of the structure looking down the axis of the DNA. The double-headed arrow in (b) indicates the nature of the conformational change that is required to open and close the clamp during binding and release of the DNA.

scissile phosphate oxygens. An interaction between a lysine residue and the base of the nucleotide where cleavage occurs is also important for catalysis. Religation is likely to proceed by a pathway that is essentially the reverse of cleavage.

Rotational Mechanism for Strand Passage

Examination of the crystal structure of human topoisomerase I (Figure 4(a)) suggests that the strand-passage reaction required to change the linking number of the DNA during DNA relaxation occurs by a rotational mechanism rather than by the enzyme-bridging mechanism described previously for the type IA enzymes. However, based on the structure there appeared to be insufficient space within the confines of the enzyme to accommodate unrestricted rotation of the DNA. This prediction was confirmed by single-molecule experiments showing that rotation was hindered by friction between the DNA and the enzyme cavity and that the number of supercoils relaxed per nicking-closing cycle depended on the amount of supercoiling torque present in the DNA.

Cellular Roles

Although much is yet to be learned about how the various topoisomerases collaborate to manage DNA topology in the cell, a partial picture has emerged based on work in bacteria and simple eukaryotes. Although the type II topoisomerases are not the subject of this article, the activities of these enzymes are briefly considered in the sections to follow for the sake of completeness. The type II enzymes are important for any cellular process that requires the passage of a region of duplex DNA through a double-strand break in the same or a different DNA molecule. The allocation of functions to the known topoisomerases in setting the global levels of supercoiling, in transcription and in DNA replication, is discussed next.

Types of Supercoiling in Eukaryotic versus Prokaryotic Cells

Two different situations lead to the supercoiling of DNA *in vivo*. First, DNA will assume a supercoiled configuration through an interaction with certain proteins or other cellular components. Alternatively, a closed domain of DNA (e.g., a closed circular DNA) will spontaneously supercoil if the linking number is not the same as the helical winding (referred to as twist) of the DNA helix. A closed DNA with this latter type of supercoil is said to be torsionally strained. The chromosomal DNA of eukaryotes is wrapped into a protein-constrained solenoidal superhelix in nucleosomes and, except for the transient occurrence of torsionally strained supercoils associated with replication and transcription, is maintained in a relaxed state by DNA topoisomerases. However, in prokaryotes it appears that although some supercoils are constrained by virtue of an interaction with proteins as in eukaryotes, there exists, in addition, a fixed steady-state level of torsionally strained supercoiling generated by DNA gyrases (see below).

Generation of Supercoiling Stress in Prokaryotes

Mesophilic and psychrophilic bacteria

The DNA in all mesophilic and psychrophilic eubacteria and archaeobacteria contains torsionally strained negative supercoils that are introduced by the type II enzyme called DNA gyrase. It appears that this steady-state level of negative superhelicity is required to facilitate helix opening during the initiation of DNA replication and transcription. To prevent the introduction of excess negative supercoils by the gyrase, nearly all of these bacteria also contain one or two type IA DNA topoisomerases (topoisomerases I or III or both) to counteract the effects of DNA gyrase. The inability of the type IA enzymes to remove negative supercoils below a critical threshold level prevents these enzymes from completely negating the effects of DNA gyrase and is crucial for fine-tuning the negative supercoiling levels in these organisms. Some eubacteria also contain a type IB enzyme which could also balance the effects of DNA gyrase; however, the apparent ability of these enzymes to completely relax the DNA suggests that their activity would have to be regulated in some way to prevent the loss of the superhelicity generated by DNA gyrase. The observation that the eubacterial *topoisomerase IB* genes are widespread, but present in only a subset of the species in a variety of phyla (*Proteobacteria*, *Bacteroides*, *Actinobacteria*, *Acidobacteria*, and *Deinococci*), provides no clear insights regarding the intracellular role(s) of the enzyme, but does suggest that they may have been acquired by horizontal transmission. Those few archaea that contain a type IB topoisomerase (psychrophiles *Cenarchaeum symbiosum* and *Nitrosopumilus maritimus*, Table 1) curiously lack type IA topoisomerases of any kind, suggesting that there must be some way in these organisms for the IB enzyme to cooperate with the DNA gyrase to set the net intracellular supercoiling level.

Hyperthermophilic bacteria

All hyperthermophilic eubacteria and archaeobacteria possess a reverse gyrase that actively maintains positive supercoils in the chromosomal DNA. It seems that this positive supercoiling is necessary to stabilize the DNA helix against denaturation at the high growth temperatures of these organisms. The mechanism

Figure 5 Topological transformations of DNA during transcription and replication. (a) The generation of positive supercoils (+) in front of and negative supercoils (–) behind a translocating RNA polymerase during transcription are depicted. (b) Replication fork movement in a closed domain results in an overwinding of the DNA ahead of the replication fork and the interwinding of the two daughter helices to form precatenanes behind the replication fork, as shown in (b). Any precatenanes remaining at the end of replication for a circular replicon will result in the catenation of the two daughter circular molecules. A simple catenane with a single interlink is also shown.

for preventing excess positive supercoiling is not known, but it is likely that a type II enzyme that can relax positive supercoils (DNA gyrase or the archaeal topoisomerase VI) counteracts the effects of reverse gyrase to set the final steady-state level of positive supercoiling.

Transcription

During transcription, the movement of RNA polymerase along a DNA that is rotationally fixed transiently generates positive supercoils in front of the translocating polymerase and negative supercoils behind the polymerase (Figure 5(a)). The type IA enzymes present in nearly all organisms relax the negative supercoils that accompany transcription, but the mechanism for the removal of the positive supercoils depends on the organism. In prokaryotes, positive supercoils are relaxed by a type II enzyme such as DNA gyrase or in the archaea by topoisomerase VI, and, in the case of select eubacteria, probably by a combination of a type II enzyme and the type IB topoisomerase.

In eukaryotes, it is likely that the type IB DNA topoisomerase I relaxes the supercoils of both signs associated with transcription. Based on the known complete genome sequences, most eukaryotes, but not fungi or *Caenorhabditis elegans*, contain two distinct genes for type IB enzymes, one for the nuclear enzyme and a second for an enzyme that is imported into the mitochondrion to presumably function in transcription. In those eukaryotic organisms with only a single type IB gene, topoisomerase I is likely targeted to both organelles.

DNA Replication

As the two DNA strands are separated during DNA replication, the DNA helix in front of the replication fork becomes at least transiently overwound or positively supercoiled (Figure 5(b)). This overwinding of the helix has been shown to be at least partially transmitted to the region behind the replication fork to cause an interwinding of the two daughter helices. These interwindings are referred to as precatenanes (Figure 5(b)), since in a circular replicon, if any remain at the end of replication, the two daughter circular molecules will be catenated. Resolution of the overwound structure of a replicating

chromosome can be accomplished by relaxing positive supercoils in front of the fork or by decatenating (or unlinking) the precatenanes behind the moving fork, or both.

As in transcription, positive supercoils can be removed in prokaryotes by a type II topoisomerase such as the DNA gyrase, the archaeal topoisomerase VI, or, for those eubacteria and archaea that have it, topoisomerase IB. Precatenanes can be resolved by a type II topoisomerase, most notably topoisomerase IV in eubacteria or topoisomerase VI in archaea. As long as gaps exist during discontinuous DNA synthesis, precatenanes can also be unlinked in some eubacteria either by topoisomerase IB or by the potent type IA decatenating enzyme, topoisomerase III. Segregation of true catenanes lacking nicks or gaps in either of the two strands can only be accomplished by a type II enzyme.

In eukaryotes, the type IB topoisomerase relaxes the positive supercoils ahead of the replication fork and, during synthesis, can probably decatenate the precatenanes by acting at gaps in the DNA. However, most of the precatenanes and terminally interlinked or catenated structures are likely resolved by a type II topoisomerase. In mitochondria, replication-associated positive supercoils are relaxed by a type IB topoisomerase as described previously for transcription. A mitochondrial type II topoisomerase and a type IA enzyme (topoisomerase III) are likely involved in unlinking precatenanes and catenated circular DNAs that occur during mitochondrial DNA replication.

Glossary

Adenosine triphosphate (ATP) A nucleotide cofactor that supplies energy for many enzymatic processes.

Cell cycle Term used to describe the cycle by which a cell grows, replicates its genome, and divides. The cell cycle is divided into four distinct phases: G₁, a growth phase; S, the phase in which the cell duplicates (i.e., synthesizes) its genetic material; G₂, a second growth phase in which the cell prepares to divide; and M, the phase in which the cell divides (i.e., mitosis).

DNA recombination The process by which the cell reorganizes its genetic material in order to repair certain forms of DNA damage (including double-stranded DNA breaks) or promote genetic diversity.

DNA replication The process by which the cell duplicates (i.e., synthesizes) its genetic material.

DNA supercoiling The underwinding (i.e., negative supercoiling) or overwinding (i.e., positive supercoiling) of the genetic material.

Gram staining Eubacteria can be distinguished on the basis of the Gram staining test. Species that do not stain with crystal violet dye are classified as Gram negative and those that do stain with this dye are classified as Gram positive.

Topoisomerase II poison A compound that increases levels of covalent topoisomerase II-cleaved DNA complexes.

Topology A field of mathematics that deals with relationships that are not altered by elastic deformation.

Transcription The process by which the cell expresses its genetic material; the generation of messenger RNAs from a DNA template.

DNA Topology

Topological properties of DNA are defined as those that cannot be altered without breaking one or both strands of the double helix. Since DNA is comprised of two interwound nucleic acid strands and the genomes of all known organisms are very long or circular (or both), two distinct topological issues arise as a result of the double helical structure of the genetic material. Proliferating cells must be able to cope with both of these topological issues in order to survive.

The first issue is related to the torsional stress on the double helix. DNA from all species of eubacteria and eukaryotes is globally underwound ~6%. DNA under torsional stress is termed 'supercoiled', because underwound (or overwound) molecules writhe about themselves to form superhelical twists. Underwound and overwound molecules are called negatively and positively supercoiled, respectively. Negative supercoiling puts energy into the genetic material and makes it easier to separate the two strands of the double helix for replication and transcription. Thus, DNA underwinding increases the rates of these two fundamental processes. By contrast, the movement of DNA tracking systems (such as replication forks and transcription complexes) through the double helix locally overwinds the DNA ahead of their actions. Since overwinding makes it much harder to pull apart the double helix, it blocks many essential cellular processes.

The second issue is related to the extreme length of genomic DNA. Nucleic acid knots (intramolecular) and tangles (intermolecular) are formed routinely during a variety of ongoing cellular processes including DNA recombination and replication. DNA knots impair the ability to separate the two strands of the double helix and reduce the tensile strength of the

genetic material. DNA tangles must be resolved in order for daughter chromosomes to segregate properly during meiosis and mitosis. Consequently, these two topological structures can be lethal to cells if they are not resolved.

DNA Topoisomerases

In order to maintain the appropriate level of DNA supercoiling and remove knots and tangles from the genetic material, cells encode enzymes known as topoisomerases. Topoisomerases modulate these topological structures by creating transient breaks in the DNA backbone. There are two classes of topoisomerases that can be distinguished by the number of DNA strands that they cleave during their catalytic cycles. Type I topoisomerases alter DNA topology by creating a transient single-stranded break in the genetic material and facilitating controlled rotation of the double helix about (or passage of the opposite strand through) the nick. Type II topoisomerases act by generating a transient double-stranded break, through which they pass a separate intact double helix. To maintain genomic integrity during DNA cleavage, topoisomerases form covalent links between active site tyrosyl residues and the newly generated DNA termini. These covalent protein-cleaved DNA complexes, known as 'cleavage complexes', are hallmarks of all topoisomerases irrespective of enzyme classification. Since type I topoisomerases create single-stranded breaks in the genetic material, they can regulate levels of DNA supercoiling. However, since type II topoisomerases generate double-stranded breaks in the DNA backbone, they can resolve knots and tangles in addition to removing torsional stress from the genetic material.

Type II topoisomerases, which are the subject of this article, are essential to all prokaryotic and eukaryotic organisms. They are highly conserved among species, and the eukaryotic enzymes appear to be direct descendents of ancestral bacterial proteins.

Type II Topoisomerases

There are two classes of type II topoisomerases, type IIA and type IIB, which are defined on the basis of homology. With one exception, type II topoisomerases are denoted by even numerals. Bacteria encode two type IIA enzymes, DNA gyrase and topoisomerase IV. Eukaryotes, by contrast, encode only one type IIA enzyme, topoisomerase II. It should be noted, however, that vertebrate species express two closely related isoforms of the enzyme, topoisomerase II α and topoisomerase II β . Archaea and plants express the only known type IIB topoisomerase, topoisomerase VI. These individual enzymes will be discussed in detail in later sections.

Enzyme Mechanism

All type II topoisomerases interconvert different topological forms of DNA by the double-stranded DNA passage reaction depicted in [Figure 1](#), which uses eukaryotic topoisomerase II as a representative enzyme. Briefly, type II enzymes (1) bind two DNA segments, (2) create a double-stranded break in one of the segments, (3) translocate the other DNA segment through the cleaved double helix, (4) rejoin (i.e., ligate) the cleaved DNA, (5) release the translocated segment through a gate in the protein, and (6) close the protein gate, regaining the ability

to start a new round of catalysis. The scissile bonds on the two strands of the double helix that are cut by type II topoisomerases are staggered. Type IIA enzymes generate cleaved DNA molecules that contain four-base single-stranded cohesive ends at their 5'-termini, while type IIB enzymes generate molecules with two-base single-stranded ends. All of the type II topoisomerases covalently attach to the newly generated 5'-termini during the cleavage event.

Type II enzymes require two cofactors in order to carry out their catalytic double-stranded DNA passage reactions. First, they need a divalent cation for all steps beyond enzyme-DNA binding. Magnesium(II) appears to be the divalent cation that the enzymes use *in vivo*. Second, they use the energy of adenosine triphosphate (ATP) to drive the overall DNA strand passage reaction. Type IIA topoisomerases do not require ATP for either DNA cleavage or ligation. However, the binding of this nucleoside triphosphate triggers DNA translocation, and its hydrolysis to adenosine diphosphate (ADP) and inorganic phosphate (Pi) is necessary for enzyme recycling. Normally, type II enzymes bind two molecules of ATP. Although hydrolysis of the cofactor is not a prerequisite for the strand passage event, it appears that this step proceeds more rapidly if it is preceded by hydrolysis of one of the bound ATP molecules. Type IIB enzymes use ATP in a similar fashion with one important distinction: they require ATP binding as a prerequisite for DNA cleavage.

Enzyme Domain Structures

Type II topoisomerases share a number of common structural motifs that are shown in [Figure 2](#). The founding type II enzyme, bacterial DNA gyrase, is comprised of two distinct

Figure 1 The double-stranded DNA passage reaction of topoisomerase II can be separated into six discrete steps. (1) DNA binding to regions of helix-helix juxtaposition. (2) Double-stranded DNA cleavage (i.e., formation of the cleavage complex), which requires the presence of Mg^{2+} (physiologically) or other divalent metal ions. (3) Double-stranded DNA passage through the DNA gate generated by cleavage. This reaction requires the binding of two ATP molecules, and strand passage proceeds more rapidly if one of the two ATP molecules is hydrolyzed. (4) Ligation of the cleaved DNA. (5) Hydrolysis of the second ATP molecule, which allows release of the DNA through a C-terminal gate in the protein and promotes (6) enzyme turnover, which allows the enzyme to initiate a new round of catalysis. The protein (shown in blue) is based on crystallographic studies of yeast topoisomerase II. Modeled DNA helices are shown in green (horizontal) and orange (coming out of the plane of the paper).

Figure 2 Domain structures of type II topoisomerases. The domain structures of three type IIA topoisomerases, bacterial (*Escherichia coli*) DNA gyrase and topoisomerase IV, and human topoisomerase II α are shown. Regions of homology among the enzymes are indicated by colors. The N-terminal (i.e., GyrB) homology domains (blue) contain the regions responsible for ATP binding and hydrolysis. The vertical white stripes represent the three conserved motifs of the 'Bergerat fold' that define the ATP-binding domain. The central (i.e., GyrA) homology domains (green) contain the active site tyrosyl residue that forms the covalent bond with DNA during scission. For human topoisomerase II α , the variable C-terminal domain (red) contains nuclear localization sequences (NLS) and phosphorylation sites (PO₄). The Top6A (purple) and Top6B (yellow) subunits of the archaeal type IIB topoisomerase, *Sulfolobus shibatae* topoisomerase VI, are shown for comparison. The active site tyrosine residue is indicated for each enzyme.

subunits, GyrA and GyrB (molecular mass ≈ 96 and 88 kDa, respectively) and acts as an A₂B₂ tetramer. GyrA contains the active site tyrosyl residue that forms the covalent bond with DNA during scission, and GyrB contains consensus sequences for ATP binding. Bacterial topoisomerase IV is also an A₂B₂ tetramer comprised of two subunits. In Gram-negative species, these subunits were first identified as proteins required for partitioning, and are designated ParC (molecular mass ≈ 88 kDa) and ParE (molecular mass ≈ 70 kDa), which are homologous to the A and B subunits of DNA gyrase. In Gram-positive species, the subunits of topoisomerase IV are designated as the gyrase-like proteins GrlA and GrlB, respectively.

Eukaryotic type IIA topoisomerases are homologous to the bacterial enzymes. However, the two subunits have fused into a single polypeptide with protomer molecular masses ranging from ~ 160 to 180 kDa (depending on the species). The eukaryotic enzymes function as homodimers. On the basis of amino acid sequence comparisons with bacterial gyrase, each topoisomerase II protomer can be divided into three distinct domains. The N-terminal domain of the enzyme is homologous to the B-subunit of DNA gyrase (GyrB) and contains the binding site for ATP. The central domain is homologous to the A-subunit of DNA gyrase (GyrA) and contains the active site tyrosyl residue. The C-terminal domain is variable and appears to have no corresponding region of homology in DNA gyrase. This region of the eukaryotic enzyme contains nuclear localization sequences as well as amino acid residues that are phosphorylated *in vivo*.

The type IIB enzyme, topoisomerase VI, has two subunits, Top6A and Top6B (molecular masses ≈ 47 and 60 kDa, respectively), and is arranged as an A₂B₂ tetramer. Both subunits are considerably smaller than those of bacterial DNA gyrase or topoisomerase IV. Although short regions of Top6B surrounding the ATP-binding domain are homologous to portions of GyrB, and Top6A contains an active site tyrosine that is required for DNA cleavage, the primary structure of topoisomerase VI displays little similarity to the type IIA enzymes.

Prokaryotic Type IIA Topoisomerases

Eubacteria contain two distinct type II topoisomerases, DNA gyrase and topoisomerase IV. In addition, some archaeal species encode DNA gyrase.

DNA Gyrase

DNA gyrase was discovered in 1976. It was the first type II topoisomerase to be described and is the only one to retain its historical name. In contrast to all other type II topoisomerases, DNA gyrase is the only enzyme that is capable of actively underwinding (i.e., negatively supercoiling) the double helix. It accomplishes this feat by wrapping DNA around itself in a right-handed fashion and carrying out its strand-passage reaction in a unidirectional manner. The C-terminal domain of the GyrA subunit is required for the enzyme to carry out this unique function.

The negative supercoiling activity of DNA gyrase far exceeds the ability of the enzyme to remove either knots or tangles from the genetic material. Consequently, the major physiological roles of DNA gyrase stem directly from its ability to underwind the double helix. DNA gyrase plays a crucial role in opening DNA replication origins and removing positive supercoils that accumulate in front of replication forks and transcription complexes. In addition, this enzyme works in conjunction with the ω protein (a type I topoisomerase that removes negative supercoils from the double helix), to maintain the global balance of DNA supercoiling in bacterial cells.

Topoisomerase IV

It had been known for several years that the ParC and ParE proteins were necessary for proper chromosome partitioning in bacteria. However, it was not discovered until 1990 that these two subunits together constituted a type II topoisomerase.

The catalytic properties of topoisomerase IV can be distinguished from those of DNA gyrase in two important ways. First, while topoisomerase IV can remove positive and negative superhelical twists from DNA, it cannot actively underwind the double helix. Second, the ability of topoisomerase IV to resolve DNA knots and tangles is considerably better than that of DNA gyrase. Because of these differences, the physiological roles of topoisomerase IV are distinct from those of DNA gyrase. The primary cellular functions of topoisomerase IV are to unlink daughter chromosomes following DNA replication and to resolve DNA knots that are formed during recombination. Recently, it was found that topoisomerase IV removes positive supercoils from DNA more efficiently than it does negative supercoils. This ability, which requires sequences in the variable C-terminal domain, has led to speculation that the enzyme also may act ahead of DNA tracking systems to help alleviate overwinding of the double helix. However, the precise role of topoisomerase IV in this process has yet to be defined.

Eukaryotic Type IIA Topoisomerases

The eukaryotic type IIA enzyme, topoisomerase II, was discovered in 1980. Topoisomerase II can remove superhelical twists from the double helix and can resolve DNA knots and tangles. Eukaryotic species, such as yeast and *Drosophila*, encode only a single type II topoisomerase (i.e., topoisomerase II). However, as discussed above, vertebrates contain two isoforms, topoisomerase II α and topoisomerase II β . These isoforms share extensive amino acid sequence identity (~70%) but are encoded by separate genes (located at chromosomal bands 17q21–22 and 3p24 in humans, respectively). Topoisomerase II α and topoisomerase II β can also be distinguished by their protomer molecular masses (~170 and ~180 kDa, respectively).

Topoisomerase II plays a number of essential roles in eukaryotic cells and participates in virtually every major process that involves the genetic material. It unlinks daughter chromosomes that are tangled following replication and resolves DNA knots that are formed during recombination. It also helps to remove the positive DNA supercoils that are generated ahead of replication forks and transcription complexes. Topoisomerase II is required for proper chromosome condensation, cohesion, and segregation, and appears to play roles in centromere function and chromatin remodeling.

Finally, topoisomerase II is important for the maintenance of proper chromosome organization and structure, and is the major nonhistone protein of the mitotic chromosome scaffold and the interphase nuclear matrix.

It is not obvious why vertebrate species encode two distinct topoisomerase II isoforms. Enzymological differences between topoisomerase II α and topoisomerase II β are subtle and relationships between these isoforms are not well defined. The only major enzymological characteristic that distinguishes topoisomerase II α and topoisomerase II β is the fact that the α isoform removes positive DNA supercoils ~10-fold faster than it does negative, while the β isoform removes both at similar rates. As with topoisomerase IV, this ability of topoisomerase II α is embodied in the C-terminal domain of the protein.

Topoisomerase II α and topoisomerase II β have distinct patterns of expression and separate cellular functions. Topoisomerase II α is essential for the survival of proliferating cells and is regulated over both cell and growth cycles. Enzyme levels increase throughout S-phase of the cell cycle and peak at the G₂/M boundary. Topoisomerase II α is found almost exclusively in proliferating tissues, is associated with replication forks, and remains tightly bound to chromosomes during mitosis. Thus, it is believed to be the isoform that functions in growth-related processes, such as DNA replication and chromosome segregation.

Topoisomerase II β is dispensable at the cellular level but is required for proper neural development in mice. In contrast to the α isoform, the concentration of topoisomerase II β is independent of the cell cycle and this isoform is found in most cell types regardless of proliferation status. Topoisomerase II β dissociates from chromosomes during mitosis and cannot compensate for the loss of topoisomerase II α in mammalian cells. Although the physiological functions of the β isoform have yet to be fully defined, recent evidence indicates involvement in the transcription of hormonally or developmentally regulated genes.

Archaeal Type IIB Topoisomerase

In 1997, a novel type IIB topoisomerase, topoisomerase VI, was discovered in hyperthermophilic archaeal species. This enzyme has been designated as the first member of the topoisomerase IIB subfamily due to its lack of homology to previously identified type II enzymes. Topoisomerase VI is also found in some plant species.

Archaeal topoisomerase VI can relax positively and negatively supercoiled DNA and can untangle interwound double-stranded DNA molecules. Although the physiological functions of topoisomerase VI have yet to be determined, the enzyme is believed to play a role in unlinking daughter chromosomes following replication in archaeal cells.

With the exception of plants, no Top6B homolog has been identified in eukaryotic species. However, a Top6A homolog, Spo11, has been found in eukaryotes ranging from yeast to humans. Spo11 generates the double-stranded DNA breaks that initiate meiotic recombination. Like its topoisomerase relatives, Spo11 forms a covalent bond between an active site tyrosyl residue and the 5'-DNA termini generated by its scission reaction. At the present time, there is no evidence that Spo11 displays topoisomerase (i.e., DNA strand passage) activity *in vivo*.

Type IIA Topoisomerases as Therapeutic Targets

In addition to their varied and critical physiological functions, the type IIA topoisomerases are targets for some of the most active antibacterial and anticancer drugs in clinical use. These agents do not act by robbing cells of essential topoisomerase activity. Rather, drugs that target type II topoisomerases kill cells by dramatically increasing the concentration of covalent enzyme–DNA cleavage complexes that are requisite intermediates formed during the double-stranded DNA passage reaction. Normally, cleavage complexes are present at low steady-state levels and are tolerated by cells. However, conditions that significantly increase either their concentration or their lifetime trigger numerous mutagenic events.

The potential lethality of cleavage complexes rises substantially when DNA-tracking enzymes, such as polymerases or helicases, attempt to traverse the covalently bound topoisomerase roadblock in the genetic material. Such an action disrupts cleavage complexes and converts transient enzyme-mediated DNA breaks to permanent DNA breaks. These permanent breaks in the genome trigger the generation of chromosomal insertions, deletions, translocations, and other aberrations and, when present in sufficient numbers, initiate a series of events that culminates in cell death. Since the drugs that target type II topoisomerases convert these essential enzymes to potent cellular toxins that fragment the genome, they are referred to as topoisomerase poisons to distinguish them from drugs that act as catalytic inhibitors.

Antibacterial Drugs

DNA gyrase and topoisomerase IV are the targets for quinolone-based antibacterial agents (Figure 3). Quinolones are the most active and broad-spectrum oral antibacterial drugs currently in clinical use. Drugs such as ciprofloxacin are prescribed routinely for a wide variety of Gram-negative bacterial infections, including gastrointestinal tract and bone and joint infections. Ciprofloxacin is also used to treat a number of sexually transmitted diseases as well as anthrax. Newly developed quinolones, such as levofloxacin, display significant efficacy against Gram-positive bacterial infections, such as those found in the respiratory tract.

DNA gyrase is the primary cytotoxic target of quinolones in Gram-negative bacteria. However, topoisomerase IV appears to be the more important target for many of these drugs in most Gram-positive species.

Anticancer Drugs

At the present time, six topoisomerase II-targeted anticancer agents (Figure 3) are approved for use in the United States. Additional drugs that target the type II enzyme are used worldwide. Drugs such as etoposide and doxorubicin are front-line therapy for breast and lung cancers, as well as a variety of leukemias, lymphomas, and germ-line malignancies.

Approximately one-half of all cancer chemotherapy regimens contain drugs targeted to topoisomerase II. Moreover, every form of cancer that can be cured by systemic chemotherapy is treated with these agents.

Due to the high concentration of topoisomerase II α in rapidly proliferating cells, this isoform probably is the more important

Figure 3 Structures of selected antibacterial drugs targeted to DNA gyrase and topoisomerase IV, anticancer drugs targeted to topoisomerase II, and dietary topoisomerase II poisons.

target of anticancer therapy. However, circumstantial evidence suggests that the β isoform also contributes to drug efficacy.

Dietary Topoisomerase II Poisons

The most prevalent dietary topoisomerase II poisons are the bioflavonoids (i.e., phytoestrogens) (Figure 3). This diverse group of polyphenolic compounds are components of many fruits, vegetables, legumes, and plant leaves. Bioflavonoids are an integral component of the human diet and represent the most abundant natural source of antioxidants. It is believed that the dietary intake of these compounds provides a number of health benefits, including protection against cancer, cardiovascular disease, osteoporosis, and inflammation. The mechanistic basis for the physiological actions of phytoestrogens is

complex, and they have a variety of effects on human cells. However, several common bioflavonoids, including genistein and (–)-epigallocatechin gallate (EGCG), are potent topoisomerase II poisons. Genistein is abundant in soy products and is believed to contribute to the lower incidence of specific types of cancers in the Pacific Rim. EGCG is the most abundant and biologically active polyphenol in green tea, and many of the therapeutic benefits of the beverage have been attributed to this compound.

Glossary

Affinity The term for how tightly a drug binds to a receptor, expressed as the concentration of drug that occupies half of the available receptors. High affinity means that a drug will bind at very low concentrations.

Agonist A drug that binds to and activates a receptor. Dopamine is the endogenous agonist for dopamine receptors.

Antagonist A drug that binds to a receptor without activating it and, thus, prevents the binding of an agonist.

Receptor A protein, usually associated with the cell membrane, that binds a neurotransmitter or hormone and initiates a biological response.

Second messenger A chemical signal elicited by an activated receptor that transmits information within a cell. The extracellular neurotransmitter is the first messenger, and whereas some receptors transduce information about the neurotransmitter concentration into an electrical response, other receptors convert that information into altered abundance of an intracellular second messenger such as cyclic adenosine monophosphate (AMP).

Introduction

Nobel prize-winning work by Carlsson and colleagues in 1958 first demonstrated that dopamine is a neurotransmitter, rather than being only an intermediate step in the synthesis of norepinephrine, and a neurotransmitter that plays an important role in regulating motor behavior. The first pharmacological evidence for the existence of specialized receptors for dopamine was obtained 5 years later, but it was not until 1972 that the identification of dopamine-stimulated adenylyl cyclase, the enzyme that converts adenosine triphosphate (ATP) into the second messenger cyclic adenosine monophosphate (AMP), made possible the biochemical characterization of a dopamine receptor. Later that decade, further pharmacological and biochemical characterization of dopamine receptors, including their division into D1 and D2 subtypes, was made possible by the development of radioisotopically labeled ligands, or radioligands, that bind to dopamine receptors with high affinity and selectivity. What might be considered the modern era of dopamine receptor research began in 1988 with the determination of the DNA sequence and predicted protein sequence of the D2 dopamine receptor and the subsequent identification of additional dopamine receptor subtypes.

Dopamine Receptor Subtypes

Virtually all neurotransmitters and hormones activate multiple receptor subtypes – distinct classes of receptors that share relatively high affinity for a single neurotransmitter but that differ in sequence, affinity for drugs, signaling, and distribution. It is common for the distribution of receptor subtypes to overlap, so that one organ or brain region may have multiple receptor subtypes for any neurotransmitter or hormone that is present.

D1-Like and D2-Like Receptor Subfamilies

Prior to the molecular cloning of dopamine receptors, they were divided into D1 and D2 subtypes on the basis of several criteria. D1 and D2 receptors have distinct pharmacological profiles; in particular, D2 receptors have high affinity for benzamide and butyrophenone antagonists such as sulpiride and spiperone, respectively, while D1 receptors have high affinity for benzazepine antagonists such as SCH23390. D1 receptors stimulate adenylyl cyclase and cyclic AMP accumulation, while D2 receptors inhibit the enzyme. Furthermore, the D1 and D2 receptors are physically distinct. For example, there are tissues such as the anterior and intermediate pituitary gland that have an abundance of D2 receptors but no D1 receptors. Finally, it is possible to cause selective damage to cell bodies in the substantia nigra or in the neostriatum of the rat brain, using lesions that spare axons and axon terminals, and with these lesions to cause a preferential reduction in the abundance of D2 receptors (substantia nigra) or D1 receptors (neostriatum), thus demonstrating the differential localization of the subtypes on cell bodies and axon terminals in these brain regions. The molecular cloning of additional subtypes of dopamine receptors revealed the existence of two receptor subfamilies, in each of which the subtypes share D1-like or D2-like characteristics.

Molecular Cloning of Dopamine Receptor Subtypes

Following the cloning of DNA encoding receptors determined to be identical to the pharmacologically characterized D1 and D2 receptors, several additional subtypes were identified in 1990–91. DNA sequence information was a new tool for classification of receptors, in that receptors belonging to the same subfamily are more similar in DNA and protein sequence. Thus, there are many amino acids that are common in D1 and D5 receptors (Figure 1(a)), but fewer that are shared among all the dopamine receptor subtypes (Figure 1(b)).

Figure 1 Predicted amino acid sequence and membrane-spanning segments of the D1 (a) and D2 (b) dopamine receptor subtypes. The figure is oriented so that the extracellular regions of each receptor are above the shaded transmembrane helices and the intracellular regions are below. Amino acids colored red in panel (a) are shared between D1 and D5 receptors, whereas amino acids colored purple in panel (b) are shared among all of the dopamine receptor subtypes.

D1 and D5 receptors are both D1-like receptors, whereas D2, D3, and D4 receptors belong to the D2-like receptor subfamily in terms of sequence identity and affinity for drugs.

Structural Characteristics of Dopamine Receptors

Most hormone and neurotransmitter receptors are integral membrane proteins that span the cell membrane at least once, so that a portion of the receptor lies outside the cell and another portion lies inside. Dopamine receptors all belong to the superfamily of proteins called seven-transmembrane receptors because they traverse the membrane 7 times, serpentine receptors because of the manner in which they wind back and forth across the membrane, or G protein-coupled receptors because most of the effects of neurotransmitter binding to the receptors are mediated by activation of G proteins. The superfamily of seven-transmembrane receptors includes receptors for light, odors, and calcium, in addition to most neurotransmitters. Although all dopamine receptors have seven membrane-spanning regions with four intracellular domains (loops 1–3 and the carboxy terminus) and four extracellular domains (the amino terminal extension and extracellular loops 1–3), the D1-like receptors have relatively short third intracellular loops and relatively long carboxy termini compared to the D2-like receptors (Figure 1).

As illustrated in Figure 1, the presence of specific amino acid residues at certain locations across receptor subtypes, or amino acid sequence homology, is highest within the membrane-spanning regions of seven-transmembrane receptors. This is primarily because maintaining the three-dimensional structure of a receptor so that it is relatively quiescent until activated by the binding of a neurotransmitter such as dopamine requires precise packing of the membrane-spanning α -helices and a network of interhelical bonds that constrain the movement of the helices. Random mutations in these regions would be often deleterious and selected against because of the relatively high likelihood of disrupting helix packing or interhelical bonds. Within a family of receptors for one neurotransmitter or for several structurally related neurotransmitters, such as the catecholamines dopamine and norepinephrine, sequence homology also reflects the conservation of amino acids that bind the neurotransmitter; for small molecule neurotransmitters such as dopamine, these amino acids are typically in the membrane-spanning helices, which form a water-accessible binding pocket within the membrane lipid bilayer.

Although depicted as single receptors in Figure 1, the functioning holoreceptor is probably at least a dimer of two dopamine receptors. Higher-order oligomers, such as tetramers, are also likely to exist. Oligomers may be homomers composed of two or more copies of the same subunit or heteromers incorporating more than one receptor subtype. Some oligomers, such as the D1:D2 oligomer, have novel properties such as unique pharmacological profiles and distinct mechanisms of signaling.

Dopamine Receptor Subtype-Selective Drugs

D1 and D2 receptor-selective drugs have been very useful for differentiating between the behavioral and biochemical effects

of D1-like or D2-like receptor stimulation. There are numerous commercially available potent and selective D2-like receptor agonists such as quinpirole and 7-OH DPAT, and antagonists such as spiperone and nemonapride (YM-09151-2). Although there are fewer D1-like receptor-selective drugs, the selective benzazepine antagonist SCH23390 and agonists such as SKF38393 and 6-chloro-APB (SKF82958) have been used to demonstrate that blockade or stimulation of D1-like receptors has significant behavioral consequences.

There is great interest in developing drugs that differentiate between D1 and D5 receptors or among the D2-like receptors, both as research tools and because of the possibility that selective blockade or stimulation of only one subtype will be a more effective treatment for a disease that is currently treated by blockade or stimulation of the D1-like or D2-like subfamily (Table 1). It is still not possible to differentiate pharmacologically between D1 and D5 receptors, two subtypes with very similar sequence in the membrane-spanning helices (Figure 1(a)). On the other hand, the use of antagonists that are highly selective for only one of the three subtypes of the D2-like receptor subfamily, particularly for the D4 receptor, has demonstrated that dopamine binding to D3 or D4 receptors in rats has behavioral effects that are very different from D2 receptor-stimulated locomotor activation. Mice that have null mutations in the gene for one receptor subtype, and thus do not express functional protein for that subtype, have also been very useful both for evaluating the *in vivo* selectivity of putative subtype-selective drugs and for determining different behavioral effects mediated by each receptor subtype.

Dopamine Receptor Signaling

Most of the effects of dopamine receptors on cellular function are mediated by activation of heterotrimeric GTP-binding proteins called G proteins. Binding of dopamine to amino acids within the membrane-spanning helices of a dopamine receptor disrupts the interhelical bonds that hold the receptor in an inactive state. The resulting movement of one or more of the helices exposes amino acids on the cytoplasmic face of the membrane that bind to and activate G proteins. D1-like and D2-like receptors have very different signaling properties as a result of differential selection of G protein subtypes.

G Protein Coupling

Heterotrimeric G proteins are composed of α , β , and γ subunits, and are generally named according to the subtype of $G\alpha$ subunit. D1-like receptors that have been stimulated by dopamine or other D1-receptor agonists activate two G proteins that stimulate adenylate cyclase, $G\alpha_s$ and the closely related G protein, $G\alpha_{olf}$ (Table 1). (The latter G protein was first identified as mediating olfactory responses to receptors for odorants.) D2-like receptors activate the $G\alpha_i$ subtypes, named after their ability to inhibit adenylate cyclase, and the closely related G protein $G\alpha_o$. That these G proteins are substrates for adenosine diphosphate (ADP)-ribosylation by cholera toxin, which persistently activates $G\alpha_s$, or pertussis toxin, which inactivates $G\alpha_{i/o}$, has contributed importantly to determining their role in dopamine receptor signaling.

Table 1 Features of human dopamine receptor subtypes

Type of feature	Dopamine receptor subtype				
	D1	D5	D2	D3	D4
Length (amino acids)	446	477	443 ^a	400	387 ^b
Introns in coding region	No	No	Yes	Yes	Yes
G protein coupling	G α_s /G α_{off}	G α_s	G $\alpha_{i/o}$	G $\alpha_{i/o}$	G $\alpha_{i/o}$
Agonists	SKF38393 6-CI-APB	SKF38393 6-CI-APB	Quinpirole 7-OH-DPAT	Quinpirole 7-OH-DPAT PD128907	Quinpirole 7-OH-DPAT PD168077
Antagonists	SCH23390	SCH23390	L-741,626	GR 103691 U99194	L-741,7141 L-745,870
Radioligands	[³ H]SCH 23390 [¹²⁵ I]SCH23982	[³ H]SCH 23390 [¹²⁵ I]SCH23982	[³ H]spiperone [³ H]YM-09151-2	[³ H]spiperone [³ H]YM-09151-2 [³ H]7-OH-DPAT	[³ H]spiperone [³ H]YM-09151-2
Localization ^c	Caudate-putamen, cerebral cortex, substantia nigra, parathyroid gland	Hippocampus, cerebral cortex	Caudate-putamen, substantia nigra, intermediate and anterior pituitary gland	Nucleus accumbens, olfactory tubercle	Cerebral cortex, hypothalamus, olfactory bulb
Splice variants	None	None	D2 _L /D2 _S	D3nf ^d	None
Allelic variants ^e	None	Leu88→Phe Ala269→Val Pro330→Gln Cys-335→stop Asn351→Asp Ser453→Cys	Val96→Ala Pro310→Ser Ser311→Cys	Ser9→Gly	Gly11→Arg 12 bp repeat in exon 1 21 bp deletion in exon 1 13 bp deletion in exon 1 Val194→Gly 48 bp repeat in exon 3

^aLength of D2_L; D2_S is 414 amino acids long.

^bLength of the variant with two repeats (D4.2) although actual length depends on the number of repeat units, which varies from 2 to 10.

^cSelected tissues and brain regions with relatively high expression of the subtype are listed.

^dD3nf is a frame-shifted variant with D3 receptor sequence only through the fifth membrane-spanning helix. Although shorter-truncated splice variants of D3 mRNA also exist, D3nf is the only one for which expression of the protein has been demonstrated.

^eOnly variants that alter the protein sequence are listed.

Signaling Pathways

As suggested by their activation of G proteins that stimulate adenylate cyclase, most effects of D1-like receptor stimulation are mediated by increased levels of cyclic AMP and cyclic AMP-dependent protein phosphorylation. D1 receptor-stimulated protein phosphorylation alters the activity of other protein kinases, receptors, protein phosphatases, ion channels, and transcription factors. Under some conditions, D1-like receptors also activate G α_q , leading to calcium mobilization. D2-like receptors inhibit the activity of adenylate cyclase via G α_i . D2-like receptors also modulate many other signaling pathways, most of them as a result of the liberation of G-protein $\beta\gamma$ subunits that occurs when seven-transmembrane receptors activate G $\alpha_{i/o}$ proteins. G $\beta\gamma$ -regulated pathways that are regulated by stimulation of D2-like receptors include several forms of adenylate cyclase, ion channels, phospholipase C, and mitogen-activated protein (MAP) kinases. Although the basic mechanism of activation of heterotrimeric G proteins by receptors is probably the same for all receptor-G protein

combinations, for reasons that have not been determined, activation of other types of G proteins such as G α_s does not produce the same G $\beta\gamma$ -mediated signaling that is observed after receptor-mediated activation of G $\alpha_{i/o}$. D2 receptors also signal via a pathway that requires the scaffolding protein arrestin3, which recruits the protein kinase Akt and protein phosphatase 2A, leading to the dephosphorylation and inhibition of Akt.

Distribution of Dopamine Receptors

The D1 and D2 dopamine receptors are overall the most abundant dopamine receptor subtypes. The D1 receptor is expressed most highly in the brain, with lower expression in peripheral tissues such as the parathyroid gland, renal, mesenteric, and coronary vascular beds, and the kidney. Within the brain, the D1 receptor is most abundant in the caudate-putamen and other basal forebrain nuclei such as the nucleus accumbens, and is also found in the cerebral cortex and the substantia nigra

pars reticulata. The D5 receptor is expressed at much lower levels in the same basal forebrain nuclei, the cerebral cortex, and hippocampus. The D2 receptor is expressed most highly in the intermediate pituitary gland, with abundant expression also observed in the anterior pituitary and in a number of brain regions including the caudate-putamen and other nuclei of the basal ganglia, the substantia nigra *pars compacta*, and the cerebral cortex. The D4 receptor is expressed in most of the same forebrain regions as the D2 receptor and in the cerebral cortex, albeit at a lower level. Whereas the D2 receptor is most abundant in dorsal areas of the striatum, the D3 receptor is also expressed in the basal forebrain but is more abundant in the ventral nuclei (nucleus accumbens and olfactory tubercle).

Dopamine Receptor Variants

Although there are only five mammalian dopamine receptor genes that give rise to D1–5 receptors, four of the genes produce multiple receptor variants (Table 1). For example, the D2 receptor has two variants that result from alternative splicing of the RNA that is transcribed from the *DRD2* gene. The long form of the D2 receptor, D2_L, contains a 29-amino-acid insert encoded by an exon that is spliced out of the short form, D2_S. Recent evidence suggests that D2_S and D2_L might serve very different functions as autoreceptors that regulate dopamine release and as postsynaptic receptors that mediate the actions of dopamine on nondopaminergic neurons, respectively. In contrast to splice variants that are derived from a single gene sequence and that are present in everybody, there are also dopamine receptor variants transcribed from distinct gene sequences, so that each individual expresses only one or two of the two or more existing variants. For example, there are at least 27 allelic variants of the human D4 receptor that have from 2 to 10 copies of an imperfectly repeated 48 nucleotide (16-amino-acid) sequence in the third intracellular loop of the receptor. There is considerable interest in the possibility that these allelic variants also vary in functional characteristics.

Therapeutic Uses for Dopamine Receptor Agonists and Antagonists

By far, the most common therapeutic purpose for drugs that act on dopamine receptors is the use of D2 receptor antagonists for

the treatment of schizophrenia and other psychoses. D2-like receptor antagonists are also used for the treatment of nausea and vomiting, for delirium or dementia of unknown cause, and for the symptomatic treatment of hyperactive movement disorder such as Tourette's syndrome and Huntington's disease. Dopamine-receptor agonists alleviate the symptoms of Parkinson's disease and are often used in combination with the dopamine precursor dihydroxyphenylalanine (L-DOPA). The D2-like receptor agonist, bromocriptine, is used to treat hyperprolactinemia because of the inhibitory effect of anterior pituitary D2 receptors on prolactin secretion. When hyperprolactinemia results from a prolactin-secreting tumor, treatment with bromocriptine also decreases the size of the tumor. Dopamine or D1 agonists such as fenoldopam cause D1 receptor-mediated vasodilation, thus increasing glomerular filtration, renal blood flow, and sodium excretion, and are used to manage types of shock associated with low cardiac output and compromised renal function.

Dynactin

T A Schroer, Johns Hopkins University, Baltimore, MD, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Centrosome A complex organelle located at the center of many cells that is the major site of microtubule nucleation and in some cells, focusing on minus ends.

Dynein A massive, multisubunit mechanoenzyme that powers movement toward the minus ends of microtubules.

Microtubule A 25-nm-diameter hollow cytoskeletal polymer comprising 11–15 parallel protofilament strands of α/β tubulin heterodimers.

Motor An adenosine triphosphatase that performs mechanical work as part of its adenosine triphosphate hydrolytic cycle.

Processivity The ability of an enzyme to catalyze a reaction on multiple, successive subunits of a polymeric substrate.

Overview of Dynactin Composition and Structure

Dynactin contains a total of 20 individual polypeptide subunits that are encoded by 11 different genes (Figure 1). The locations and nearest neighbors of most dynactin subunits have been identified using antibody labeling and biochemical analysis (Figure 2). Most of dynactin's mass is contained in a brick-like structure that is a pentameric polymer of the actin-related protein, Arp1. The subunits p62, Arp11, p27, and p25 are organized into a cup-shaped complex that sits at one end of this polymer. The actin-capping protein (CapZ) α/β heterodimer is present at the other end of the Arp1 polymer. This end of the structure terminates in cap that most likely contains portions of the p150^{Glued}, dynamitin, and/or p24 subunits. Dynactin also contains a single monomer of conventional cytoplasmic β -actin, the precise location of which has not been rigorously defined. Dynactin uses different subunits to mediate binding to a wide variety of cellular structures.

A major structural domain of dynactin is the shoulder and flexible arm which projects approximately 20 nm from the Arp1 rod. The point at which the arm connects to the shoulder is highly flexible. This part of the dynactin molecule contains the largest dynactin subunit, p150^{Glued}, dynamitin (p50), and p24 in a stoichiometric ratio of 2:4:2. The p150^{Glued} subunit mediates interactions between dynactin, motors, and microtubules and may bind other proteins as well.

Dynactin structure has been imaged in the electron microscope (EM) by a variety of methods, including negative-staining EM and scanning transmission EM. Detailed structural information has come from platinum replicas of rotary shadowed, quick-frozen, deep-etched molecules and also averaged images of negatively stained particles. The dynactin structures obtained in this manner are the basis of the cartoon shown in Figure 2. Till the time of preparation of this entry, no high-resolution structural information about dynactin as a whole or any of its individual subunits (aside from actin, CapZ and the CAP-Gly domain of the p150^{Glued} subunit) was available.

Dynactin Functions

Functions Associated with Dynein-Based Motility

Dynactin was first discovered as a large (20S) protein complex that copurified with the minus end-directed motor, cytoplasmic dynein. Dynactin was found to be required for long-range, dynein-driven translocation of membrane vesicles *in vitro*. The name dynactin derives from this dynein-activating activity.

Adapter Function

An important function of dynactin is to serve as an adapter that allows cytoplasmic dynein to bind a variety of cargoes. This adapter function highlights the importance of dynactin's distinct dynein and cargo-binding domains. Dynein is the predominant minus end-directed motor activity in most cells, so virtually any subcellular structure or macromolecular complex that moves toward the cell center, or toward microtubule minus ends in a noncentrosomal array, is translocated by dynein in conjunction with dynactin. Dynein cargoes include membranous organelles such as Golgi-derived membranes, the ER–Golgi intermediate compartment (ERGIC), early, late, and recycling endosomes, lysosomes, and mitochondria. Dynein can also move lipid droplets, aggresomes, intermediate filaments, RNA–protein particles, viral capsids, and centrosome components toward microtubule minus ends.

Dynactin also contributes to the binding of dynein to large cellular structures such as centrosomes, mitotic spindle poles, chromosomes, the nucleus, and the plasma membrane. Dynein associates with centrosomes beginning in S-phase and remains at spindle poles during mitosis. Centrosomal dynactin is required for dynein binding. The persistent action of dynein at spindle poles is required for the retention and organization of microtubules. Dynactin is also required for proper binding and function of dynein at chromosome kinetochores, which is important for capture of spindle microtubules in prometaphase and poleward movement of kinetochore-associated mitotic regulators. Dynein may also power lateral sliding of chromosomes along microtubules and help maintain end-on attachment of chromosomes to microtubules that undergo

Figure 1 Dynactin composition. Dynactin's 11 distinct polypeptide subunits are shown on this Coomassie blue-stained, SDS polyacrylamide gel.

Figure 2 Subunit organization in dynactin. The three different binding domains are indicated. The precise location of conventional actin is unknown.

disassembly at their plus ends during prometaphase and anaphase. In some cell types, dynactin and dynein are recruited to the outer nuclear membrane just prior to mitosis. Dynein-driven movement of the nuclear envelope along microtubules pulls the entire centrosomal microtubule array toward the nucleus. This causes centrosomes to become closely associated with the nuclear surface and contributes to nuclear envelope rupture.

Dynein binds to the cell cortex via dynactin. As in the case of dynein bound to the nuclear envelope, the force exerted by cortical dynein 'reels in' microtubules, pulling with them any structures to which they might be attached. This process can reorient the entire microtubule array relative to the cell surface and contributes to the long-range movements of nuclei that occur during mitosis and cellular morphogenesis.

Processivity Enhancement

In the absence of dynactin, individual cytoplasmic dynein molecules are able to travel only short distances along the microtubule lattice. Dynactin's p150^{Glued} subunit provides additional microtubule binding sites that help hold dynein

near the microtubule. This allows dynein to move over longer distances, making it a more processive motor. Dynactin acts in a similar manner to enhance the processivity of kinesin-2, and may also contribute to the activity and function of other kinesin family motors.

Dynein-Independent Functions

Dynactin has the potential to support nonmotile interactions of microtubules with cellular components in a manner that is independent of motor binding. This cross-linking function depends on dynactin's distinct microtubule and cargo-binding domains. Dynactin associates with microtubules at their plus ends, their minus ends, and may even bind along their length. At plus ends, dynactin may help control the rate of microtubule growth and shrinkage by recruiting or working with other plus end-binding factors. Dynactin is also seen at sites where microtubule minus ends converge, such as centrosomes, at times when dynein is not. At this site, dynactin contributes to microtubule anchoring. Dynactin may interact with microtubule minus ends directly, or it might bind other minus end-binding or centrosome-associated proteins. Subunits of dynactin's cargo-binding domain are able to associate with a wide array of intracellular molecules and macromolecular complexes that are still being identified. This may allow dynactin to tether these structures to microtubules in a transient manner, suppressing free diffusion and helping localize them at particular sites within the cell. This may be a mechanism for holding signaling molecules in the cytoplasm and out of the nucleus.

Structure and Function of Individual Dynactin Subunits

Structure

Dynactin subunits can be grouped into four structural families: (1) proteins whose structures resemble actin (actin itself, plus the actin-related proteins Arp1 and Arp11) or actin-binding proteins (CapZ), (2) elongated, largely α -helical proteins (p150^{Glued}, dynamitin, and p24), (3) β -helix proteins (p25 and p27), and (4) Cys/His RING/LIM domain proteins (p62).

Actin-Related or Actin-Binding Proteins

Dynactin contains three proteins of the actin superfamily: β -(cytoplasmic) actin, Arp1, and Arp11. Arp1 is very similar (~65% identical) to conventional actin and is the only Arp that has been shown to assemble into filaments. Arp11 is less similar to actin but can copolymerize with actin and bind Arp1 *in vitro*. Sequence comparisons suggest that Arp11 is most divergent at its pointed end face. Arp11 is bound directly to the pointed end of the Arp1 filament to block further subunit addition. The CapZ species found in dynactin contains the β_2 isoform only. Among the dynactin subunits, these five dynactin polypeptides are the most highly conserved between species.

Elongated α -Helical Proteins

The polypeptides p150^{Glued}, dynamitin, and p24 are the least highly conserved of all the dynactin subunits, suggesting that

Figure 3 Two representations of the domain organization of p150^{Glued}. Top: a schematic of the primary sequence with predicted structural features and known and potential interaction sites indicated. The microtubule-binding (MT) region contains a CAP-Gly motif and a basic motif that have both been implicated in microtubule binding. Bottom: a cartoon illustrating the N-terminal globular heads plus the location and approximate lengths of the two coiled-coil domains. The structural features of the open-boxed regions have not been determined.

their overall structures play a more important role in dynactin function than their specific sequences. p150^{Glued} forms a parallel homodimer that is stabilized by two coiled coils, one ≥ 200 amino acids long and the other ~ 125 amino acids long (Figure 3). The 200-amino-acid N-terminal domains comprise the globular heads at the tip of the projecting arm. This part of p150^{Glued} supports microtubule binding via a CAP-Gly (i.e., cytoskeleton-associated protein, glycine-rich) domain and basic motif. The structure of the CAP-Gly domain (AA ≈ 40 –110) has been determined and is similar to other CAP-Gly domains. Only AA ≈ 1 –350 are exposed in the projecting arm, leaving the rest of the p150^{Glued} molecule to associate with other dynactin subunits to form the shoulder that sits on one side of the Arp1 filament. The structural features of the p150^{Glued} central region and C terminus have not yet been defined, but the middle portion (AA ≈ 520 –1050) is relatively hydrophobic and likely to be buried. The p150^{Glued} messenger RNA (mRNA) is subject to alternative splicing which yields proteins that show differential microtubule-binding properties. p150^{Glued} splice isoforms may also interact differentially with motors and other cellular components.

Dynamitin is a major structural component of the dynactin shoulder and is fundamentally important to the structural integrity of dynactin. Its sequence (AA ≈ 100 –406) predicts multiple α -helices that participate in intra- and intermolecular coiled-coil and multicoil interactions with other shoulder subunits. By itself, recombinant dynamitin forms elongated, flexible oligomers (trimers or tetramers), but it adopts a more compact structure when associated with the dynactin subunit, p24. The dynamitin N-terminus binds to Arp1 directly. Free dynamitin is able to displace p150^{Glued} from the Arp1 filament and is, thus, a powerful experimental tool that is widely used to inhibit dynactin-based phenomena *in vivo*.

β -Helix Proteins: p25 and p27

The opposite end of the dynactin molecule terminates in a complex of four proteins, Arp11, p62, p27, and p25. p27 and p25 are evolutionarily related and contain a repeated polypeptide motif that is predicted to fold into a β -helix, a structure not commonly found in animal proteins. Known β -helix proteins

are elongated triangular prisms that possess an extended binding face or groove on one face of the prism. The short β -helices in p25 and p27 may dimerize via side-to-side association to form a compact structure, or they may associate with end-to-end to form longer-binding face. Both p27 and p25 contain a loop that is predicted to project away from the β -helix prism and a C-terminal extension. p27 is subject to mitotic phosphorylation which may be a means for regulating dynactin function across the cell cycle.

RING/LIM Domain Protein: p62

Very little is known about p62 structure, but it has been shown to associate with actin, Arp11, and Arp1 and is necessary for dynactin's structural integrity. p62 contains a Cys/His-rich motif of the RING/LIM type that may indicate an associated E3 ubiquitin ligase activity. p62 contributes to the mechanism by which dynactin binds the nuclear envelope at the onset of mitosis.

Binding Activities

Dynactin can interact with a wide variety of cellular components. Its binding partners can be grouped into three major categories: (1) microtubules, (2) motors, and (3) cargoes that undergo microtubule-dependent movement or tethering. Each type of interaction is supported by a different part of the dynactin molecule (Figure 2).

Microtubule Binding

The ability of dynactin to bind microtubules is believed to contribute to its activity as processivity factor or dynein and other motors and may also allow it to serve as a tethering factor for nonmotile structures. Two distinct motifs present in the N-terminal head at the tip of the p150^{Glued} arm (Figure 3) contribute to microtubule binding. The well-known CAP-Gly motif found in a number of microtubule-binding proteins allows p150^{Glued} to associate with EB-family proteins that associate with microtubule plus ends. The adjacent basic motif is thought to support low-affinity direct interactions

with microtubules. Binding may be regulated by phosphorylation at a site that lies between these two motifs.

Motor Binding

p150^{Glued} is also the major motor-binding subunit. Its best-characterized binding partner is cytoplasmic dynein, but p150^{Glued} has been reported to interact with the kinesin family motors, Eg5, and kinesin-2. Motors bind to the central portion of p150^{Glued} (amino acids ~430–800; **Figure 3**) and phosphorylation may play a regulatory role. It is not known whether this element contains one or more motor-binding site and whether other dynactin subunits are involved.

Binding to Other Cellular Components

Membranes

Dynactin localizes to and contributes to the motility of a wide variety of cellular membranes, including the Golgi complex and associated vesicles, ERGIC, TGN, numerous elements of the endocytic pathway, the nuclear envelope, and the plasma membrane. Membrane binding involves Arp1 filament components. Arp1 associates with the actin-binding region of at least one spectrin isoform, which might provide a general binding mechanism. Binding to recycling endosomes requires the p27 and p25 subunits, whereas nuclear envelope binding utilizes p62 and Arp11.

Other Cytoplasmic Structures

The association of dynactin with lipid droplets, intracellular pathogens, RNA–protein particles, and cytoplasmic signaling complexes also appears to involve the Arp1 filament domain. In most cases, binding mechanisms have not yet been defined.

Chromosomes

Dynactin is bound to chromosome kinetochores during mitosis. As in the case of other structures that bind dynactin, kinetochore binding probably involves multiple dynactin subunits. One known contributor to this interaction is dynamitin, which has been reported to bind the kinetochore component, ZW10, directly.

Dynamic Behavior of Photosystem II Light Harvesting

P Horton, University of Sheffield, Sheffield, UK

© 2013 Elsevier Inc. All rights reserved.

This article is a revision of the previous edition article by Peter Horton and Alexander Ruban, volume 3, pp. 357–362, © 2004, Elsevier Inc.

Glossary

Grana membrane The characteristic organization of the chloroplast thylakoids in which regions of membrane become tightly appressed together to form stacks of membranes, associated with the lateral segregation of the photosystems.

Nonphotochemical quenching The quenching of chlorophyll fluorescence that arises because of an increase in thermal dissipation of excitation energy, contrasted to the photochemical quenching that arises because energy is used to drive photosynthetic electron transfer.

Photoinhibition The inhibition of photosynthesis that arises during excess illumination, either from

sustained quenching of antenna or reaction center complexes or from accumulation of damaged photosystem II D1 proteins.

State transitions The reversible adaptation of the light-harvesting system to differential excitation of photosystem I (PSI) and PSII; in state 1, induced by over excitation of PSI, energy transfer from LHCII to PSII is maximum, and in State 2, induced by overexcitation of PSII, energy transfer from LHCII to PSI is maximum.

Xanthophyll cycle The reversible de-epoxidation of thylakoid-bound violaxanthin to zeaxanthin, via the intermediate antheraxanthin.

The light-harvesting proteins of higher plants play a vital role in the regulation of photosynthesis. These proteins show striking structural and functional flexibility. This dynamic behavior provides a key physiological function to plants, which adapts them to continuously changing environmental conditions. In particular, dynamic properties of the light-harvesting proteins of photosystem II (PSII) promote the efficient collection of sunlight when the intensity is limiting photosynthesis and effective photoprotection when the intensity is excess.

Photosynthetic Light Harvesting

PSII is the multisubunit chloroplast membrane-associated pigment–protein complex that uses the energy of sunlight to drive the oxidation of water, evolving oxygen, donating electrons into the photosynthetic electron transfer chain, and depositing protons into the thylakoid lumen. Along with the PSI, it forms the electron–proton transfer chain, which drives the synthesis of adenosine triphosphate (ATP) and reduced nicotinamide adenine dinucleotide phosphate (NADPH) (Figure 1). Vitrally important components of both photosystems are the light-harvesting antennae, the light-collecting units (mainly LHCI and LHCII for PSI and PSII, respectively) that ensure high rates of energy input into the photosynthetic reaction centers (RCI and RCII, respectively) by intercepting large numbers of light quanta of various energies/colors.

The light-harvesting antenna of PSII consists of several proteins, which together bind around 300 chlorophyll molecules. Associated tightly with the D1/D2 reaction center are the core antenna complexes CP47 and CP43. The remainder of the antenna consists of the Lhcb proteins, Lhcb1–6. These bind chlorophyll *a*, chlorophyll *b*, and xanthophylls to form several

different complexes – LHCII (Lhcb1–3), CP29 (Lhcb4), CP26 (Lhcb5), and CP24 (Lhcb6). LHCII is the main complex and contains about 40% of the PSII chlorophyll – it is the most abundant chlorophyll protein in nature. Lhcb1, Lhcb2, and Lhcb3 associate in different combinations to form a population of heterotrimeric LHCII, which show different strengths of binding to the PSII core complex.

A single Lhcb monomeric unit is a relatively small protein, ~25 kDa, containing three transmembrane alpha-helical structures (A, B, and C helices) and binding up to 12 molecules of chlorophyll (up to 7 chlorophyll *a* and 5 chlorophyll *b*) and up to four xanthophylls. In the case of LHCII, two xanthophylls, lutein 1 and 2, are associated with the helices A and B. A third carotenoid, neoxanthin, is associated with the helix C and the trimer also binds peripherally the carotenoids violaxanthin or zeaxanthin (Figure 2). *In vivo*, two PSII reaction center complexes form the dimeric PSII core complex, which may bind up to four trimeric LHCII and six monomeric CP24, CP26, and CP29. In the photosynthetic membrane, these PSII units are sometimes seen as ordered arrays, their frequency reflecting the regulation of PSII function as explained below. The LHCII antenna forms a dynamic network, or macrodomain, of monomeric and trimeric subunits, associated with each other and the reaction-center complex. Associated with this macrostructure is the stacking of the complexes together in the characteristic grana membranes.

Three major parameters determine the efficiency of light harvesting: (1) the absorption cross section (or number of pigments) and their ability to intercept light quanta with the broad range of energy; (2) the time during which energy of light can be kept in antenna so it can be funneled into the reaction center; and (3) rate of the funneling. Thus, a large cross section, long-excitation-energy lifetime, and high rate of energy transfer to the reaction center are the attributes of an efficient antenna and productive photosynthetic unit. Hence,

Figure 1 The photosynthetic light-harvesting and electron transfer system. PSII and PSI both served by light-harvesting antenna drive the oxidation of water and the reduction of NADP, connected by an electron transfer chain consisting of plastoquinone (PQ), the cytochrome *bf* complex (Cytbf) and plastocyanin (PC). H^+ release into the thylakoid lumen results in formation of a ΔpH , the driving force for ATP synthesis. Shown are the dimeric and monomeric core complexes of PSII and PSI (gray), the antenna protein of PSI, Lhca1-4 (mixed green), and PSII, Lhcb1, Lhcb2 (pale green), Lhcb3 (dark green), Lhcb4 (blue), Lhcb5 (yellow), Lhcb6 (red). Two types of LHCII trimers are shown – strongly bound S-trimers of Lhcb1, Lhcb2 and more weakly bound M-trimers containing Lhcb3.

Figure 2 Structural model of LHCII monomer as revealed by X-ray crystallography. The dominant feature of the structure are the three α -helices (gray), which provide the scaffold for the binding of chlorophyll *a* (green) and chlorophyll *b* (blue) molecules. The four xanthophylls are shown: N1 (neoxanthin), L1 and L2 (luteins), and V1 (violaxanthin).

the efficiency of light harvesting in PSII is determined by the number of LHCII subunits, the pigment order within them, the interaction between subunits, and their closeness to the reaction center complex.

The Need for Control of the Light Reactions of Photosynthesis

The light and dark reactions of photosynthesis are tightly coupled, the ATP and NADPH provided by the electron-proton transfer system driving the fixation of CO_2 into carbohydrate. There are dramatic diurnal changes in the spectrum of sunlight reaching the leaf surface due to filtering by atmosphere, clouds, and other plants. As LHCI and LHCII have different capacities to absorb light of different wavelengths, there will be a frequent imbalance in light energy input into PSI and PSII reaction centers. This imbalance would decrease the efficiency of electron transfer, and hence the overall quantum yield of photosynthesis. The light intensity is also a very changeable parameter, varying a 1000-fold. Whenever light input exceeds the capacity of electron transport and CO_2 assimilation, there is an excess of light, which may cause photoinhibition – the destabilization (by overreduction and overenergization) and even damage (by photooxidation and generation of reactive-oxygen species) to photosynthetic components, mainly in PSII. The effects of such changes in light are amplified by alterations in photosynthetic capacity brought about by changes in other environmental factors (such as low temperature or drought), or by changes in metabolic demand, which result in variation in the rate of turnover and the stoichiometry of ATP and NADPH.

To achieve balance and stability of the photosynthetic process, regulatory mechanisms are necessary. The plant cell first has to assemble a chloroplast with the correct composition, and then various parts of the photosynthetic process need to be able to adjust their activities in response to internal and external information. Thus, light harvesting, electron transport, and carbon metabolism can be considered to be linked by a feedback and feedforward control network, which operates at the levels of gene expression, protein turnover, covalent modification, and protein activity. There is a compromise between maximizing the collection and utilization of light, and the avoidance of instability when light is in excess. The most appropriate way of looking at the regulatory mechanisms is that, given a fixed composition and a fluctuating environment, they extend the range of conditions over which photosynthesis can remain in balance – they provide homeostasis of excitation energy level, redox state, and ΔpH .

Two distinct regulatory strategies optimize light-harvesting function. The first balances the input of light energy to PSI and PSII reaction centers in order to optimize electron transfer rate – this is called the state transition. The second regulates the amount of light energy directed to PSII – this is called nonphotochemical energy dissipation or quenching (NPQ). Both regulatory mechanisms take place within the LHCII system and rely on its abilities to sense the state of the light-energy balance and to structurally respond, being capable of dynamic behavior.

State Transitions

The Lhcb1 and Lhcb2 polypeptides of LHCII are reversibly phosphorylated by a redox-regulated thylakoid-associated protein kinase, STN7. Phosphorylations at threonine residues near the N terminus of LHCII weaken the association between

PSII and LHCII, as a result of electrostatic and conformational changes (Figure 3). Phospho-LHCII partitions in favor of PSI, this association depends on the presence of the PSI-H subunit – in mutants without PSI-H phospho-LHCII remains associated with PSII. These changes in association between LHCII and the two photosystems may take place primarily (or only) at the grana periphery, and may not involve long-distance migration between appressed and unappressed membranes. Conversely, limited diffusion of complexes in the plane of the thylakoid membrane may be promoted under conditions of LHCII phosphorylation. Certain specific LHCII trimers seem to be preferentially dissociated from the PSII complex and the kinetics of the state transition are correspondingly influenced by the exact composition of the Lhcb proteins. The kinase is activated when the plastoquinone pool is reduced, this being sensed by the plastoquinol oxidation site on the cytochrome *b₆f* complex. The kinase, therefore, monitors the relative rates of delivery of excitation energy to PSII and PSI; overexcitation of PSII (state 1) activates the protein kinase, decreases delivery of excitation energy to PSII, and increases transfer to PSI (state 2). Levels of LHCII phosphorylation are lower at high light compared to low light, showing that the state transitions optimize photosynthesis in limiting light. This includes not only optimizing linear electron transport, but also the provision of optimal ΔpH and ATP/NADPH ratios by controlling the proportion of cyclic electron transfer around PSI.

Figure 3 The state transitions. (a) Kinetic model showing how overexcitation of PSII relative to PSI in state 1 leads to electron buildup in the PQ pool (blue arrows), activating the thylakoid STN7 protein kinase (PK), which phosphorylates LHCII. Phosphorylated LHCII (LHCII-P) transfers its energy to PSI (state 2), thereby correcting the imbalance. (b) Structural basis of the state transitions. Phosphorylation of a subpopulation of LHCII trimers, leads to its dissociation from the PSII complex and its attachment to PSI, thereby increasing its absorption cross section. Color coding of subunits as in Figure 1.

Nonphotochemical Energy Dissipation

Energy-Dependent Quenching, qE

Dissipation, or quenching, of excess excitation energy absorbed by LHCII occurs by two processes, distinguished by the speeds with which they are induced upon exposure to illumination, their relaxation times in darkness, and their light intensity thresholds. The major process under normal conditions is called qE, because it depends upon the energization of the thylakoid membrane as a result of ΔpH formation (Figure 4). Thus, the progressive increase in ΔpH that occurs as light saturation of photosynthesis is reached is the trigger for energy dissipation. It can, therefore, be referred to as feedback de-excitation. The formation of qE occurs within seconds to minutes of exposure to excess light, and relaxes with a similar rate in darkness. By contrast, the sustained qI-type of quenching may take several minutes or even hours to appear and relax, and under some conditions (such as low temperature) may be stable for days.

The Site of Quenching

Application of mathematical models for PSII energy transfer to simple chlorophyll fluorescence measurements showed that quenching associated with qE occurred in the light-harvesting antenna. Analysis of the chlorophyll fluorescence lifetimes showed that qE is best explained by the transition between two states of the antenna, with different rate constants for energy dissipation. Spectroscopic data and biochemical analysis confirmed that the PSII antenna was the site of quenching. A powerful way to determine which proteins are involved in qE is to investigate plants deficient in specific components. Experiments using plants deficient in all of the Lhcb proteins suggested that qE was not a property of the core antenna. However, plants in which Lhcb1 and Lhcb2, Lhcb3, Lhcb4, Lhcb5, and Lhcb6 have been separately reduced to less than 5% wild-type levels of protein by antisense technology or to zero by knockout mutation all show qE, albeit with reduced levels and/or altered kinetics. It is concluded that qE is not confined to a single complex, but rather is a property of several working together. A major landmark in qE research was the identification of the *npq4* mutant, a mutant lacking qE and which is deficient in the Lhc-related protein PsbS. This four-helix protein is located in PSII, and contains protonatable amino acid residues that are thought to play some part in sensing the thylakoid lumen pH. It remains unclear how PsbS carries out its function in qE, but there is evidence that it acts indirectly, controlling the transition of the antenna from the unquenched to quenched states.

The Xanthophyll Cycle

Under conditions of excess light, violaxanthin is de-epoxidized to zeaxanthin via the monoepoxide antheraxanthin due to the activation of violaxanthin de-epoxidase, a thylakoid lumen enzyme. Another enzyme, zeaxanthin epoxidase reverses the reaction in low light. A vast amount of data, from a wide variety of plant species under many different environments, showed correlations between the extent of qE and the deepoxidation state of the xanthophyll cycle pool. Zeaxanthin is an

Figure 4 Nonphotochemical quenching. (a) Kinetic model showing how the ΔpH , the signal of excess light, triggers the protonation of the light-harvesting antenna (resulting in the NPQ state, qE) and also stimulates the de-epoxidation of bound violaxanthin to zeaxanthin. The pK_a of the V-form is lower than that of the Z-form, so that V and Z are allosteric regulators of qE. (b) A possible structural basis of qE regulation: under the influence of the PsbS protein (black), partial dissociation of the PSII complex occurs, leading to aggregation of Lhc subunits (pale blue) in which quenching centers are created. De-epoxidation then favors the formation of the NPQ state. The proportion of PSII complexes forming semi-crystalline domains (not shown) may control how many PSII complexes are available for switching into the NPQ state. (c) A quenching center in LHCII, depicting the role of Lutein 1 as the quencher within a chlorophyll *a* domain (a610, a611, and a612). A conformational change in neoxanthin occurs as the complex switches from the light-harvesting state into the NPQ state.

activator of qE in that the apparent pK_a of the protonation reaction inducing qE shifts from near 4.5 to well over 5.0 in the presence of zeaxanthin. As the ΔpH *in vivo* does not fall below 5.5, qE will depend almost completely on de-epoxidation of violaxanthin. Therefore, qE is an allosteric process, under the control of the interacting effects of protonation and zeaxanthin binding, similar to a regulated enzyme (Figure 4(a)). This mode of regulation explained how the chloroplast could have a ΔpH high enough in limiting light to allow ATP

synthesis without qE, yet in saturating light, how to have maximum electron transport rates and high qE simultaneously. Similarly, the variable sensitivity of qE to ΔpH explains the kinetics of NPQ when plants are transferred from dark adaptation into light: an initial rapid phase of quenching reflecting the baseline response to ΔpH , is followed by a slow phase as violaxanthin is de-epoxidated and qE activated; then a second illumination after brief dark adaption sees NPQ form rapidly in one phase, reflecting the activated response of qE to ΔpH .

It has proved difficult to completely distinguish between the proposal that zeaxanthin was directly involved in quenching chlorophyll-excited states by chlorophyll/zeaxanthin energy transfer, and the notion that zeaxanthin was working indirectly, modifying or inducing a quenching process intrinsic to the PSII antenna.

The Nature of the Quenched State of LHCII

Changes in the absorption spectra of chlorophyll and carotenoid occur upon formation of qE. A band with a maximum at 535 nm (ΔA_{535}) has attracted most attention, because its appearance is perfectly correlated to the amount of quencher. Resonance Raman spectroscopy of leaves and chloroplasts has shown that ΔA_{535} is electronic in origin, and arises from a pool of one or two zeaxanthin molecules per PSII, which undergo a strong red shift in the presence of ΔpH .

Analysis of fluorescence lifetimes shows that the qE state of the PSII antenna has a lifetime of around 0.5 ns and the unquenched state 2.0 ns. Experiments with isolated light-harvesting complexes have shown how such a change can arise. Detergent-solubilized LHCII has a lifetime of 4 ns, but reduction of the detergent concentration causes formation of strongly quenched oligomers with an average lifetime of 0.3 ns. This quenching has many features that are similar or identical to qE, and it is thought that the local environment in the grana membrane tunes the state (and lifetime) of the antenna complexes to give rise to those found *in vivo*. The spectral changes in chlorophyll accompanying this *in vitro* quenching, indicate that a particular LHCII domain is involved, and transient absorption spectroscopy has shown that protein-bound xanthophyll participates in the quenching mechanism (Figure 4(c)). The *in vitro*-quenched state can also be investigated by reconstitution of light-harvesting complexes with altered carotenoid content. Studies on such complexes again point to a quenching mechanism involving xanthophylls.

In general, the ease with which LHCII *in vitro* can adopt a quenched state reflects the high density of pigment within it. Its design as a light-harvesting complex means it maximizes the amount of chlorophyll per unit volume. Specific features of protein structure are needed to control the interactions between pigments, to promote energy transfer and to prevent formation of quenchers – dimers or excimers of chlorophylls and/or chlorophyll–xanthophyll associates. Therefore, only rather small changes in structure are needed to allow a quencher to form. Indeed the activation energy for the formation of a quencher in LHCII indicates the breakage of just a couple of H bonds. Thus, LHCII is uniquely poised to allow a switch between an unquenched state functioning in

photosynthetic energy capture and a quenched state, dissipating excess energy as heat. Single-molecule spectroscopy of LHCII has shown how this intrinsic switching arises from inherent molecular disorder that allows structurally very similar but functionally very different states.

The Role of Thylakoid Suprastructure in LHCII Regulation

The dynamic behavior of LHCII occurs within the grana membranes of the chloroplast. Here, there is a flexibility in the macroorganization of the LHCII–PSII supercomplexes. Complexes can associate into areas of regular crystalline arrays or of more random organization. There appears to be sufficient mobility of complexes in the plane of the membrane to allow a dynamic equilibrium between different associations between complexes and their subunits. For example, qE may require the complexes to be in a random organization in which clustering and associations between Lhcb subunits can take place under the influence of the protonation exposed residues on thylakoid lumen surface (**Figure 4(b)**), just as the state transitions are regulated by changes in stromal surface charge due to phosphorylation (**Figure 3(b)**).

Biological Diversity of qE

The amount of qE in different plants is highly variable. High-light-grown plants may have 2–3 times more qE capacity and plant species adapted to growing in stressful environments have a much higher qE capacity than those inhabiting milder conditions. Genetic manipulation to increase the level of the PsbS protein results in an increase in qE, suggesting that the level of this protein is an important determinant of qE capacity.

Algae exhibit different qE properties to higher plants. In *Chlamydomonas*, qE is smaller and forms more slowly and mutation of an LHCII subunit decreases the capacity of qE, suggesting that here a less-efficient process is controlled directly by the antenna and not by PsbS. In diatoms, which have light-harvesting proteins of a different type, qE can be much larger than in higher plants, and its formation and relaxation totally depend upon the de-epoxidation of the violaxanthin analog, diadinoxanthin. It seems that some features of the molecular mechanism for the regulation of light harvesting have diverged during evolution of classes of organisms.

Other Responses of LHCII to Excess Light

The sustained qI-type of quenching appears to also result, in part at least, from alteration in the antenna of PSII. At low temperature, strong quenching is induced by light which has some features diagnostic of an increase in aggregation state of LHCII – formation of a red-shifted fluorescence emission band at 77 K. This state of LHCII seems to be semi-permanent in some evergreen plants during winter. The mechanism by which such quenching is formed is currently unknown. At elevated temperature, increased light-induced quenching arises from a different process – LHCII dissociates from PSII to be quenched

by PSI, in a process that resembles the state transition, and, in fact, phosphorylation of LHCII and elevated temperature act synergistically.

When plants grown under low light are exposed to a sustained increase in light intensity, LHCII degradation is induced. Only monomers can be the substrates for proteolysis, and so this process must be preceded by a light-induced breakdown of trimers. Little is known about the biochemistry or regulation of this proteolytic process. Under extreme conditions, not only LHCII but also complete photosystems are degraded as the plants seek to minimize oxidative damage.

The content of LHCII varies significantly depending on the light intensity under which the plants are grown. Typically, a low-light-grown plant may have four to five trimers per PSII core complex, whereas in high light this reduces to one to two. The extra LHCII in low-light plants appears to be present in membrane domains deficient in PSII core complexes. These LHCII domains can still be involved in efficient energy transfer, even transferring energy to pigments on opposite membranes in the grana.

The adjustment of the composition of photosystem II upon growth in high light compared to low light maintains the redox potential and ΔpH at the correct level, optimizing photosynthesis and avoiding oxidative stress. At higher growth irradiance, when LHCII cannot decrease any more, there are increases in the capacity for photoprotection (e.g., through an increase in xanthophyll-cycle activity or PsbS content) and, eventually, decrease in the chlorophyll content of the leaf in order to lower light absorption. Such acclimation to light conditions involves gross changes in chloroplast composition and is costly in terms of energy and time. Thus, one may look upon the short-term dynamics of the LHCII antenna as buffering the effect of environmental perturbation, extending the range over which photosynthetic efficiency and photoprotection can be maintained without alteration in composition.

Even macroscopic events such as chloroplast movements or changes in leaf orientation can be similarly viewed as contributing to the optimization of light-harvesting and counteracting photodamage. Thus, plants do whatever they can, by a multitude of mechanisms, to limit the level of excitation energy in the PSII antenna, giving balance with the demands of photosynthesis, and optimizing the redox state and ΔpH . Such regulation is driven by the survival and fitness of plants: it has been questioned whether the optimization observed in economically important crop plants is adapted to high productivity. Thus, there is interest in exploring whether retuning the dynamics of LHCII could bring about increases in crop yield.

Glossary

AAA+ ATPase Superfamily of ATPases associated with diverse cellular activities found in all kingdoms of living organisms.

Axoneme Cytoskeletal structure of the cilia and flagella composed of nine outer doublet microtubules with dynein arms and radial spokes, and two central microtubules with central pair projections.

Head Globular C-terminal portion of the dynein heavy chain containing six AAA domains and the microtubule binding stalk. It is the smallest portion of the heavy chain that has ATP-dependent microtubule binding.

Linker The region of the N-terminus of the heavy chain that links the Tail/stem to AAA domain 1 of the head. Movement of the linker plays an important role in dynein movement along microtubules.

Microtubule A cytoskeletal polymer of tubulin dimers in approximately 13 protofilaments arranged as a hollow tube with two distinct ends, the plus and minus ends.

Tail/stem N-terminal region of the dynein heavy chain binds most other subunits of the dynein complex and can participate in dimerization with one or more other heavy chains.

Characteristics of Dynein Complexes

Dyneins are found in many eukaryotes, including fungi, worms, insects, and vertebrates, but genome sequence analyses indicate that they are not present in flowering plants. Dynein complexes are composed of one to three heavy chains, and each complex also has various smaller accessory subunits (Tables 1 and 2). Dyneins are classified as either cytoplasmic or axonemal. The green alga, *Chlamydomonas*, which has two flagella, has been a useful model system for studies of axonemal dyneins. These dyneins are the arms which project from the doublet axonemal microtubules of flagella and cilia. The axonemal dyneins generate the sliding force between outer doublet microtubules that is converted by other axonemal structures into the bending of cilia and flagella. The axonemal dyneins are further divided into the outer arm and inner arm dyneins defined by their position of the outer doublet microtubules. Of the more than ten different dynein complexes identified in animals, most are components of the flagellar axoneme. Various organisms, from yeast to mouse, have been utilized for studies on cytoplasmic dynein. Cytoplasmic dynein 1 moves membranous organelles, kinetochores, and viruses along microtubules. It is also the motor for retrograde axonal transport and is involved in the assembly and function of the mitotic spindle. The second type of cytoplasmic dynein, cytoplasmic dynein 2, is responsible for a component of intraflagellar transport (IFT), specifically the transport of protein complexes from the tips of cilia and flagella to their base, that occurs between the axonemal microtubules and the flagellar membrane. This dynein is often referred to as IFT dynein.

The different dynein complexes hydrolyze MgATP at different rates, for example, the microtubule stimulated ATPase activity of bovine brain cytoplasmic dynein is $0.3 \text{ mol min}^{-1} \text{ mg}^{-1}$ and the activity of axonemal outer arm dynein is $2.0 \text{ mol min}^{-1} \text{ mg}^{-1}$. Different dynein complexes also move along microtubules at different rates. An *in vitro* motility assay is used to quantify the velocity of dynein-based movement

by using computer-enhanced video microscopy. Dynein is attached to a glass coverslip and when microtubules are added, the dynein motor domains bind the microtubules. In the presence of MgATP, the dynein moves microtubules across the coverslip with the microtubule-plus ends leading. Cytoplasmic dynein from bovine brain moves microtubules at the rate of approximately 1 $\mu\text{m/s}$ while sea urchin outer arm dynein moves microtubules at the rate of 3.5 $\mu\text{m/s}$.

The Dynein Heavy Chain

The central component of the dynein complex is the heavy chain, an approximately 530,000 Da polypeptide, and it is a relative of the AAA+ ATPase superfamily. Sometimes the heavy chain alone is mistakenly referred to as a dynein. The C-terminal two-thirds of the heavy chain, approximately 350,000 Da, is necessary for ATP-dependent microtubule binding. Structural analyses indicate that the C-terminal motor portion forms a large globular domain known as the head (Figure 1) made up of six sequential AAA domains. Projecting from the head as a stalk between AAA domains 4 and 5 is the microtubule binding region, approximately 350 amino acids long, consisting of a globular region between two antiparallel coiled coils. AAA domains 1 through 4 contain consensus nucleotide-binding sites known as Walker A motifs, or P loops, while AAA domains 5 and 6 lack nucleotide-binding motifs. AAA 1 is the site of ATP hydrolysis for force generation. In the presence of vanadate and inorganic phosphate, the heavy chains are cleaved by photolysis with ultraviolet light into two fragments in AAA 1. Experimental evidence indicates that the nucleotide-binding activities associated with AAA domains 2, 3, and 4 are involved in the regulation of the motor activities, including microtubule binding and ATPase activity. The extreme C-terminus of the heavy chain spans a region from AAA domain 6 toward the stalk. The N-terminal portion of the heavy chain extends from the head at AAA

domain 1 as a flexible linker that continues as the stem or tail. Movements of the lever arm-like linker and the stalk play key roles in the conversion of the energy released by ATP hydrolysis at AA1 into dynein movement along a microtubule.

Two or three dynein heavy chains can interact via their N-terminal tails to form a common base. Most of the other subunits of the dynein complexes bind to the N-terminus of the heavy chain at the tail and these subunits contribute to the motor protein's cargo binding domain, or base. The axonemal and cytoplasmic dynein heavy chains can be distinguished by comparing the Walker A motifs of AAA domains 1–4. Genome analyses indicate that generally there are approximately 14

axonemal dynein heavy chain genes, one cytoplasmic dynein 1 heavy chain gene, and one cytoplasmic dynein 2 heavy chain gene. Axonemal outer arm dynein complexes are composed of two or three different heavy chains depending on the species. Each axoneme has many different inner arm dyneins. One inner arm dynein is a heterodimer of two different heavy chains, and there are at least six different monomeric inner arm dyneins each with one copy of a unique heavy chain. The cytoplasmic dynein complexes are homodimers of their unique heavy chains.

Cytoplasmic Dyneins

Cytoplasmic Dynein 1

The mammalian cytoplasmic dynein 1 (Figure 1 and Table 1) has a native molecular weight of 1.5×10^6 Da. It is a homodimer of two identical heavy chains (DYNC1H1) associated with two approximately 74 kDa intermediate chains (DYNC1I1), two approximately 55 kDa light intermediate chains (DYNC1LI1), and three pairs of light chains (8–12 kDa), the Tctex1 (DYNLT), roadblock (DYNLRB), and LC8 (DYNLL) families. The heavy chain is encoded by a single gene and in vertebrates all the other subunits are encoded by two genes. Additional intermediate chain and light intermediate chain isoforms are also generated by mRNA alternative splicing. The multiple gene products enable the cell to produce functionally different cytoplasmic dynein complexes; for example, in neurons, signaling endosomes bind to dynein complexes with a specific intermediate chain isoform.

The heavy chain dimerization domain is a large portion of its N-terminal tail. Also in this region are the overlapping

Table 1 Composition of cytoplasmic dynein complexes^a

Subunit	Cytoplasmic dynein 1	Cytoplasmic dynein 2 (IFT)
Heavy chain	DYNC1H1 (HC)	DYNC2H1
Intermediate chain	DYNC1I1 (IC1) DYNC1I2 (IC2)	DYNC2I1
Light intermediate chain	DYNC1LI1 (LIC1) DYNC1LI2 (LIC2)	DYNC2LI1
Light chains

^aOf the several different nomenclatures used to identify inner arm dyneins, only one is presented here, except for that of the dimeric (two-headed) inner arm dynein. Monomeric inner arm dyneins with different heavy chains, but shared light chains, are grouped for simplicity.

From King SM and Kamiya R (2009) Axonemal dyneins: Assembly, structure, and force generation. In: Witman GW and Harris EH (eds.) *The Chlamydomonas Source Book*, Vol. 3, *Cell Motility and Behavior*, 2nd edn., pp. 31–208. Oxford: Elsevier/Academic Press.

Figure 1 Model for the structure of cytoplasmic dynein 1. The heavy chains (blue) have a C-terminal head (light blue) with six AAA domains (numbered); the far C-terminus (C dark blue) forms a separate seventh domain of the head. A microtubule binding domain (MTB) projects from each head at the tip of a stalk (dark blue). The N-terminus of the heavy chain extends from the head at AAA domain 1, as the linker region (dark blue) along the ring of AAA domains; the N-terminal region then continues as the tail/stem which dimerizes and binds the light intermediate chains (LICs) and the intermediate chains (ICs). The three light chain dimers bind the intermediate chains.

binding sites for the light intermediate chain dimers and the intermediate chain dimers. The intermediate chain plays an important scaffold role in the structure of the cytoplasmic dynein complex. In addition to binding the heavy chains, the intermediate chain binds the three light chain families, as dimers. It also binds other proteins including the p150 (Glued) subunit of dynactin, a protein that links dynein to its cargo. The intermediate chain has seven WD domains at its C-terminus which are necessary for binding to the heavy chain. The intermediate chain N-terminus is a region predicted to form a coiled coil and following it are the alternative splicing regions. The binding site for the dynactin subunit, p150, is in the N-terminal coiled coil region. The Tctex1 and LC8 light chains bind the intermediate chain just down from the alternative splicing region, while the Roadblock light chain binds upstream of the first of the WD domains. The intermediate chain dimerization domain is between the LC8 and Roadblock light chain-binding regions. The LC8 light chain is also a component of the axonemal outer arm dynein and the two-headed inner arm dynein. LC8 is not only associated with dyneins. It is also a component of myosin V, axonemal radial spokes, and it is important for the proper folding and function of many cytoplasmic proteins.

Cytoplasmic dynein 1 has many functions in cells. It is important for the transport of many different membranous organelles, maintaining Golgi position near the centrosome, endosome movement, and nuclear migration. During mitosis, dynein assists in the assembly of spindle poles, is used by kinetochores to move along microtubules, and generates pulling force from the cell cortex to separate the spindle poles.

In axons, cytoplasmic dynein is essential for retrograde membrane-bound organelle movement in fast transport and for the movement of microtubules and neurofilaments. Several viruses including adenovirus, herpes, and HIV also utilize cytoplasmic dynein to move along microtubules during the infection process. The cytoplasmic dynein cargo-binding domain at the far N-terminus of the heavy chain includes the intermediate chains, light intermediate chains, and the three light chain families. The best-characterized protein responsible for linking dynein to cargo is the dynactin complex; it is important for dynein binding to kinetochores and most membrane-bound organelles. Dynactin also increases cytoplasmic dynein processivity, the distance a dynein travels along a microtubule before detaching. Cytoplasmic dynein may also transport individual proteins which bind directly to the various subunits. The cytoplasmic dynein heavy chain, light intermediate chain, and intermediate chain subunits are phosphorylated *in vivo*. Light intermediate chain phosphorylation is correlated with cell-cycle regulation of dynein binding to membrane-bound organelles. Intermediate chain phosphorylation reduces its binding affinity for the p150 subunit of dynactin *in vitro*.

In fungi, deletion mutations of dynein subunit genes are not lethal, but mitosis is disrupted. Deletion of the cytoplasmic dynein heavy chain is lethal in multicellular organisms such as mouse and *Drosophila*. Nonlethal mutations of cytoplasmic dynein subunits result in axonal pathfinding defects and other pleiotropic developmental defects in *Drosophila*. A dominant mutation in the mouse heavy chain results in age-dependent progressive degeneration of motor neurons as well as pathfinding defects in heterozygotes. The protein encoded by human genetic brain disorder lissencephaly, Lis1, binds to and regulates the function of cytoplasmic dynein.

Cytoplasmic Dynein 2 (IFT Dynein)

The heavy chain of cytoplasmic dynein 2 was initially identified by molecular studies as a heavy chain closely related to the cytoplasmic dynein 1 heavy chain, yet one whose expression level was unregulated during flagellar synthesis. Further study showed that the primary function of cytoplasmic dynein 2 is to be the motor for one direction of IFT. It moves protein complexes from the flagellar tip to the base in the space between the outer double microtubules and the flagellar membrane. It is thus required for the formation of most flagella including sperm flagella. The cytoplasmic dynein 2 structure is similar to that of cytoplasmic dynein 1. It is homodimer of the heavy chain and has its own intermediate and light intermediate chains, although the only light chain component identified to date is LC8. The green alga *Chlamydomonas*, which does not contain a cytoplasmic dynein 1, but does have two flagella, has been a useful model system for the study of cytoplasmic dynein 2.

Axonemal Dyneins

Dyneins are the motor proteins that drive the bending of cilia and flagella. The axonemal dyneins are attached to the outer doublet microtubules of axonemes and generate the sliding

force between neighboring outer doublet microtubules that is the basis for the propulsive bending of flagella that move cells through fluids. The base of an axonemal dynein binds to one of the axonemal outer doublet microtubules, the A microtubule. A dynein head binds to the B microtubule of the neighboring outer doublet in an ATP-sensitive manner and utilizes the hydrolysis of ATP to push the B microtubule toward the tip of the axoneme. The arms are arranged in two rows along the microtubules, the outer and inner arms, and the dyneins in each row are different and have different functions. The outer arms specify the flagellar beat frequency and the inner arms specify wave form. *Chlamydomonas* has 14 axonemal dynein heavy chain genes, and eight different axonemal dynein complexes have been purified from their flagella to date. There is one outer arm dynein complex and seven well-characterized different inner arm complexes (Table 2).

Outer Arm Dyneins

The *Chlamydomonas* outer arm dynein is a heterotrimer of three different heavy chains; however in some species, such as sea urchin, the outer arm is a heterodimer. The outer arm dynein also has two different intermediate chains and up to 11 light chains. Outer arm dynein binds to the microtubule through the outer arm docking complex. Although they bind to different cargo, the intermediate chains of outer arm dynein are closely related to that of cytoplasmic dynein 1. The C-termini of the intermediate chains, the region which interacts with the heavy chains, are well conserved. However, their N-termini are different and that is thought to allow the binding to the different cargos. Also present in the outer arm dynein are: a member of the Tctex1 light chain family, LC9; the Roadblock family light chains, LC7a & b; and LC8 light chain family members, LC6, LC8, and LC10. The other outer arm dynein light chains have also been well characterized. LC3 and LC5 are thioredoxin homologs. LC4 is involved in the regulation of dynein by Ca^{+2} and LC2 is Tctex2. LC1 is a member of a leucine-rich repeat family, and unlike the other light chains, it binds to the motor domain of the gamma heavy chain, not to its N-terminus and it functions as a conformational switch to control outer arm activity.

Inner Arm Dyneins

The inner arm dyneins are very heterogeneous (Table 2). Inner arm dynein 1 has two different heavy chains, three different intermediate chains, and three light chains, including Tctex1 and LC8. The other six inner arm dyneins have a single unique heavy chain and associate with different sets of light chains. All associate with conventional actin and several associate with p28 and centrin. The functional significance of the association of actin with these dyneins is unknown.

To convert from dynein-driven microtubule sliding to flagellar bending, only a subset of the axonemal dyneins functions at one time. The axonemal dyneins must be regulated. The phosphorylation state of the inner arm dynein intermediate chain IC138 modulates this regulation. Genetic analysis has also identified several proteins that make up a dynein regulatory complex, though the mechanism of the complex remains unknown.

Glossary

Autacoid A class of physiologically active substances that act upon the cell that elaborated this compound or on adjacent cells.

Cyclooxygenase (COX) Enzymes that catalyze the oxidation of arachidonic acid. Also known as ‘prostaglandin H (PGH) synthase’. COX catalyzes two sequential reactions, a *bis* oxygenase, or cyclooxygenase, reaction leading to the formation of PGG₂ and a subsequent peroxidase activity at the C15 position leading to the conversion of PGG₂ to PGH₂.

Eicosanoid Any of the collections of oxygenated metabolites of the 20-carbon fatty acid, 5,8,11,14-eicosatetraenoic acid (arachidonic acid) that are the products of cyclooxygenase, cytochrome P450, lipoxygenase, and nonenzymatic pathways.

G-protein-coupled receptors (GPCRs) A class of integral membrane protein cell-surface receptors that change conformation upon binding cognate agonists. This conformational change causes the dissociation of heterotrimeric G proteins leading to the initiation of the signal transduction cascade.

Leukotriene Monooxygenated metabolites of arachidonic acid formed by the action of lipoxygenases.

Nonsteroidal anti-inflammatory drugs (NSAIDs) A class of drugs that effect their action by inhibiting the activity of cyclooxygenase. They have potent analgesic, antipyretic, and anti-inflammatory properties.

Prostanoids Oxygenated metabolites of the 20-carbon essential fatty acid arachidonic acid. They are analogs of the 20-carbon unnatural fatty acids, prostanoic, and thrombanoic acid, produced by the action of cyclooxygenase.

Eicosanoids are the oxygenated metabolites of the 20-carbon polyunsaturated fatty acid arachidonic acid. These compounds are locally acting autacoids and are rapidly metabolized with a half-life of minutes to seconds. Once formed, eicosanoids exert their physiologic effects via interaction with specific receptors. The best characterized of these receptors belong to the superfamily of G-protein-coupled receptors (GPCRs), although some eicosanoids are thought to interact with nuclear hormone receptors as well.

Eicosanoid Biosynthesis Pathways

The 5,8,11,14-eicosatrienoic acid, a 20-carbon polyunsaturated fatty acid with the trivial name arachidonic acid, is esterified in the lipid bilayer of cell membranes. Upon its enzymatic release by the action of phospholipase, free arachidonate is rapidly metabolized. Oxygenated metabolites of arachidonic acid are collectively known as the ‘eicosanoids’. These

compounds are formed by the action of three distinct enzymatic pathways.

The Lipoxygenase Pathway

This pathway leads to the formation of the monooxygenated compounds such as hydroperoxytetraenoic acids (HPETEs), hydroxytetraenoic acids, and trihydroxylated metabolites known as ‘lipoxins’ via three principal enzymes: 5-lipoxygenase (LO), 12-LO, and 15-LO. The 5-HPETEs are substrates for the leukotriene synthases that lead to the formation of a series of key inflammatory mediators, the leukotrienes, including the unstable intermediate LTA₄, which is converted to the potent mediator LTB₄ and the cysteinyl leukotrienes LTC₄, LTD₄, and LTE₄. Sequential oxidation of arachidonic acid by the action of both 12-LO and 5-LO or 12-LO and 15-LO leads to the formation of the lipoxins LXA₄ and LXB₄. The lipoxins are structurally related to the leukotrienes, but appear to act through a distinct set of receptors and have very different actions *in vivo*.

Finally, the 5-LO metabolite HPETE can be further metabolized to the 5-oxo-EETE (5-oxo-6E,8Z,11Z,14Z-eicosatetraenoic acid), for which a unique receptor has recently been cloned.

The Cyclooxygenase Pathway

Cyclooxygenase (COX) metabolism leads to the production of the five principal prostanoids via two distinct isozymes, COX-1 and COX-2. Four of the principal prostaglandins (PGs), PGE₂, PGD₂, PGF_{2α}, and PGI₂ are analogs of the 20-carbon unnatural fatty acid prostanoid acid, which is distinguished by its five-carbon prostane ring group comprised of carbons five through eight. The fifth prostanoid, thromboxane, has an inserted ether oxygen and thus has a six-member ring structure and is an analog of the unnatural fatty acid thrombanoic acid.

The Epoxygenase Pathway

Oxidation of arachidonic acid by the cytochrome P450 pathway leads to the formation of epoxytrienoic acids (EETs). Although physiologic effects have been attributed to these compounds, no specific EET receptors have been identified to date.

Eicosanoid Action

As a class, eicosanoids mediate a wide array of physiologic effects including pain, inflammation, and modulation of smooth muscle tone. Many of these effects are receptor-mediated by cell surface GPCRs. There is recent evidence that some PG metabolites can activate nuclear hormone receptors of the peroxisome-proliferation-activated receptor family (PPARs). In addition to the enzymatic products of arachidonic acid metabolism, prostanoid-like products resulting from nonenzymatic oxidation have also been described and designated isoprostanes. These products are structurally related to the COX-derived prostanoids, but are the product of nonenzymatically free radical oxidation. Isoprostanes are markers of oxidative stress and evidence suggests that these metabolites can also evoke receptor-mediated physiologic effects.

Receptors of Lipoxigenase Metabolites

The action of LO metabolites of arachidonic acid is mediated by a distinct family of GPCRs. Six GPCRs have been identified that bind LO metabolites of arachidonic acid: four leukotriene receptors designated BLT₁, BLT₂, CysLT₁, and CysLT₂ have been described, a lipoxin receptor designated ALX, and the receptor for 5-oxo-EETE.

Leukotriene Receptors

The leukotriene receptors fall into two groups of structurally related GPCRs: the chemoattractant-like BLT receptors and the CysLT receptors, which are related to the family of

nucleotide-binding receptors. Of the four cloned leukotriene receptors, BLT₁ and BLT₂ receptors have highest affinity for the leukotriene LTB₄ with BLT₁ binding LTB₄ with much higher affinity as compared to BLT₂. The BLT receptors are predominantly expressed in the peripheral blood including leukocytes, granulocytes, macrophages, and eosinophils. The CysLT₁ and CysLT₂ receptors in contrast each bind the cysteinyl leukotrienes LTC₄ and LTD₄ with high affinity. CysLT receptors are expressed in peripheral blood leukocytes, spleen, and lung as well in a number of other tissues at lower levels. The CysLT₁ receptor has been implicated as an important mediator in asthma, and antagonists of this receptor such as montelukast have been used clinically in the treatment of asthma.

Lipoxin Receptors

The lipoxin A₄ receptor (ALX), is a member of the GPCR family of chemoattractant receptors, as are the BLT receptors discussed above. This receptor was identified as an orphan receptor complementary DNA (cDNA) sharing significant homology with the formyl-methionine-leucine-phenylalanine (FMLP) chemoattractant receptor and was designated FMLP-like receptor 1 (FPLR1). Subsequent identification of this receptor as a mediator of LXA₄ action resulted in its designation as the ALX receptor. Activation of this receptor mediates the anti-inflammatory actions of lipoxin LXA₄. Northern blot analysis of ALXR messenger RNA (mRNA) in mouse tissues demonstrates that the receptor is most highly expressed in neutrophils, lung, and spleen with lower levels detected in the liver and heart. Some actions of lipoxins cannot be accounted for by the ALXR, and the existence of other lipoxin receptors has been postulated, but existence of other lipoxin receptor cDNAs has not been confirmed.

The 5-oxo-EETE Receptor

The orphan GPCR TG1019 and closely related R527 have been identified as receptors for 5-oxo-EETE. These receptors have no official designation at this time. These receptors have been shown to be highly expressed in the kidney and may mediate the observed hemodynamic effects of 5-oxo-EETE described in this tissue.

Prostaglandin Receptors

The local action of PGs depends in part, on activation of a family of specific GPCRs, designated EP for E-prostanoid receptors, FP, DP, IP, and TP receptors respectively, for the other prostanoids. The EP receptors are unique in that four receptors, designated EP1 through EP4, have been described for PGE₂ each encoded by a distinct gene. A second class of prostaglandin D receptor designated chemoattractant receptor-homologous molecule expressed on Th2 cells (CRTH2) has been identified, which has no sequence homology to the remaining PG receptors. This receptor has been unofficially designated

Figure 1 EP₃ receptor sequence of three mouse EP₃-receptor splice variants differing only in their intracellular carboxyl termini. The predicted amino acid sequences of each splice variant is represented by the one-letter amino acid code. Exons are color coded. The common region is comprised of two exons (in white and red circles) which are spliced to three possible C-terminal tails. The carboxyl variable tails are designated alpha (blue), beta (gray), and gamma (yellow), each encoded by distinct exons.

DP2. Each of the other PGs has a single receptor, and taken together there are nine PG GPCRs, each encoded by distinct genes. Alternative mRNA splice variants have been cloned for the EP1, EP3, TP, and FP receptors. In each case, these splice variants generate receptor sequence diversity in the intracellular C-terminal tail of the receptor protein (Figure 1). Functionally, these splice variants appear to modulate the specificity of G-protein coupling, as well as regulation of receptor desensitization by encoding alternate phosphorylation sites. Pharmacologically, the PG receptors are distinguished by their ligand-binding selectivity as well as the signal transduction pathway they activate. In general, PG receptors may have significant affinity for more than one prostanoid ligand. Moreover, multiple PG receptors are frequently coexpressed in a single cell type or tissue. COX activation and resulting PG production may lead to complex effects in the target tissue by activation of multiple PG receptor subtypes. Thus, a given PG ligand may elicit multiple, and at times apparently opposing, functional effects on a given target tissue. For example, PG receptors were initially characterized by their actions on smooth muscle,

where they may lead to either smooth muscle contraction or relaxation. The vasodilator effects of PGE₂ have long been recognized in both arterial and venous beds. Smooth muscle relaxation by PGE₂ is, however, not uniformly observed, and PGE₂ is a potent constrictor in other smooth muscle beds, including trachea, gastric fundus, and ileum. Importantly, some structural analogs of PGE₂ are capable of reproducing the dilator effects of PGE₂, but are inactive on tissues where it is a constrictor. Conversely, analogs that reproduce the constrictor effects of PGE₂ may fail to affect tissues where PGE₂ is a dilator. The EP receptor mRNAs exhibit differential expression in a number of tissues with distinct functional consequences of activating each receptor subtype. Functional antagonism among PGs can also be observed in platelet aggregation, where TXA₂ activation of the TP receptor causes platelet aggregation. Conversely, prostacyclin (PGI₂) activates platelet IP receptors which opposes this platelet aggregation. Thus, the balance of PGs synthesized as well as the complement of PG receptors expressed determines the net effect of COX metabolism on platelet function.

PPARs

In addition to the GPCR-mediated effects, there is evidence that PG metabolites are capable of activating some nuclear transcription factors. This action is exemplified by the cyclopentenone PGs of the J-series, for example, 15-deoxy- Δ 12, 14-PGJ₂ (15d-PGJ₂) which are derived from PGD₂. 15d-PGJ₂ activates a nuclear hormone receptor designated peroxisome proliferation activated receptor gamma. There is also evidence that PGI₂ also activates another member of this family designated PPARdelta. It is unclear whether the PGs represent true endogenous ligands of these receptors, as their affinity is generally in the micromolar range, which is two to three orders of magnitude lower than the nanomolar affinities observed for PGs at the GPCRs; nonetheless, these concentrations could be achieved in the intracellular environment.

Glossary

Cyanogen bromide A chemical reagent used to cleave peptide bonds adjacent to methionine residues.

Desmosine A pyridinium ring alkylated in four positions; it serves as a cross-link derived from four lysine residues.

Lathyrism A disease caused by ingestion of seeds of *Lathyrus odoratus*, a sweet pea. The active agent

is β -aminopropionitrile which inhibits lysyl oxidase.

PolyA tail A string of adenine nucleotides added to the 3' end of most eukaryotic messenger RNAs.

Promoter A DNA sequence that binds RNA polymerase resulting in transcription initiation.

Svedberg unit (S) A unit used for the sedimentation coefficient; equivalent to 10–13 s.

Elastin is a protein that exists as fibers in the extracellular spaces of many connective tissues. Elastin derives its name from its ability to act as an elastic band, that is, to stretch and recoil with transient force. It is located throughout many tissues and organs of higher vertebrates and plays an important functional role in maintaining pressures associated with liquid and air flow in the cardiovascular and pulmonary systems. Elastogenic cells synthesize and secrete a soluble monomeric form of elastin into the extracellular space. The enzyme, lysyl oxidase, initiates cross-linking of the soluble monomers into insoluble fibers. Extracellular elastin associates closely with other proteins in the matrix, including microfibrillar proteins and collagens. Once laid down in the matrix, the insoluble protein is very stable and resistant to degradation. Because of its critical role in the normal development and function of vital organs, either impairment of elastin synthesis or proteolytic degradation of the insoluble fibers results in major clinical pathologies.

Composition and Primary Sequence

Elastin, as any protein, possesses a unique amino acid composition and a unique sequence of those amino acid residues along the polypeptide chain.

Amino Acid Composition

The soluble form of elastin, sometimes referred to as tropo-elastin, contains a preponderance of uncharged and nonpolar amino acids. The polypeptide chain contains approximately 850 amino acids and a molecular mass of 65–72 kDa. The actual size varies somewhat among different species. Glycine (33%), alanine (18%), proline (13%), valine (17%), and leucine (5%) residues represent 86% of the total amino acids. Prolyl hydroxylase converts 1–2% of the proline residues to hydroxyproline but it is unclear as to the significance of this cotranslational modification. There are ~36–38 lysine residues per molecule, so the overall charge of monomer is basic with an isoelectric point over pH 10. Once lysyl oxidase deaminates the epsilon amino group of most lysine residues in the protein, the resulting semi-aldehydes undergo a series of aldol

condensations and Schiff bases to form the desmosine cross-links. At this stage, the protein is irreversibly insoluble and any success in extracting soluble fragments requires cleavage of peptide bonds.

Amino Acid Sequence

Unlike the classical triple repeat of collagen wherein glycine residues occupy every third position of the triplet, elastin does not contain a uniform repeating structure. Instead, elastin contains two broad sequence motifs that accommodate much subdivision. Most lysine residues segregate together with alanine residues to create pairs of lysines separated by two or three alanine residues. These sequences exist within stretches of uncharged, nonpolar amino acid residues such as glycine, valine, and proline. The latter amino acid residues occur together with other nonpolar, hydrophobic, and polar residues, form tri, tetra, penta, and hexa repeats with not a single consistent motif. The carboxy terminal sequence is unique and highly conserved among different species. It contains the only cysteine residues within the molecule.

Isolation of Elastin

Insoluble Elastin

An early operational definition of elastin was that it represented the protein remaining, after one extracted all other connective tissue proteins. Consequently, the insolubility of elastin serves as the basis for all isolation methods. Isolation procedures involve very harsh treatments such as autoclaving, extraction with hot alkali or strong denaturants, and exposure to cyanogen bromide or collagenases. Amino acid analysis of the material remaining insoluble after these treatments confirms the presence and homogeneity of the elastin.

Soluble Elastin

In vivo the conversion of soluble to insoluble elastin occurs rapidly, making the isolation of soluble elastin very difficult. In order to isolate quantitative amounts of soluble elastin from a tissue, one must block the conversion of the soluble to the

insoluble form. Inhibition of the cross-linking enzyme, that is, lysyl oxidase, is the most effective approach for isolating intact elastin monomers. As lysyl oxidase is a copper-dependent enzyme that is specific for lysine residues, it can be inhibited by removing copper or adding a noncompetitive inhibitor. In practice, this involves rendering an animal copper deficient by dietary restriction or by adding β -aminopropionitrile, a lathyrogen, to the diet of young animals. The procedure for isolating soluble elastin is based primarily on its unique solubility in organic solvents.

The Elastin Gene

Gene Structure

The single-copy, elastin gene spans ~35–40 kb of DNA but only 7% of the sequences represent exons that are transcribed into the messenger RNA (mRNA). The huge amount of intron sequences in the gene (19:1, intron to exon) makes this one of the most disperse genes reported. The short exon sequences (<190 bp) encode separate cassettes for the nonpolar and lysine/alanine residues of the protein. Many of the intron sequences encode elastin-like sequences.

Gene Promoter

The elastin gene promoter contains features of a constitutively expressed (housekeeping) gene. It lacks a classic TATA box, is very GC rich (67%), has two CAAT boxes, and possesses multiple transcription start sites. There are also several Sp1 sites as well as a cryptic GC box and several consensus AP2 sequences within the proximal promoter. In addition, consensus sequences for glucocorticoid, TPA-inducible, and CRE response elements reside in the distal promoter regions.

Elastin Gene Expression

Elastin mRNAs

Transcription of the elastin gene results in multiple mRNAs. All the multiple forms possess a size in the 24S range arising from alternate splicing of several different exons. All of the transcripts contain ~3.5 kb that includes a large untranslated 3' region of ~1.0 kb in addition to the polyA tail.

Elastin Protein Isoforms

Translation of multiple mRNA results in different isoforms of soluble elastin that reflect insertion of different exon sequences. Although there is variance in the presence of isoforms dependent on cell type and age, the function of the different variations of soluble elastin is still not clear. There is speculation that different isoforms play a major role in the early phase of elastic fiber assembly by providing interactive sites for specific binding to other components of the extracellular matrix.

Regulation of Elastin Gene Expression

The expression of elastin is high in developing tissues and through early growth to maturity. In the adult animal, elastin

synthesis is very low and its reinitiation occurs only in normal injury/repair situations or in some pathological conditions. Many studies have focused on understanding how elastin expression is regulated in development and disease conditions. The results show that expression is regulated at both the transcriptional and the posttranscriptional levels.

Transcriptional Regulation

Many studies have shown that elastin expression in developing pulmonary and cardiovascular tissues is controlled primarily at the transcriptional level. These results have been confirmed in transgenic animals carrying the transgene with a reporter driven by the elastin promoter and by *in vitro* tissue transfections of the same reporter gene. In addition, primary cultures of elastogenic cells demonstrate that elastin transcription plays a major role in the action of elastin modulators, such as basic fibroblast growth factor and insulin-like growth factor. Putative *cis*-acting elements in the 5' flanking region of the gene have been broadly defined through transient transfections of various cell types with a series of deletion reporter constructs. Of the *cis*-acting elements identified within the elastin promoter, few have been functionally shown to convey an increase in elastin transcription. In fact, majority were found to be repressors. These latter observations suggest that a possible route to increase elastogenesis is to block the repressor complex from binding via the disruption of the receptor and/or ligand binding, as well as blocking the resultant signal pathway.

Posttranscriptional Regulation

Studies on the expression of elastin in cultures of elastogenic cells challenged with biologically significant factors show that elastin mRNA stability is important in regulating expression, especially in the adult animal.

Glossary

Arachidonic acid Common name for eicosatetraenoic acid (eicosatetraenoic acid, 20:4 $\Delta^{5,8,11,14}$), an essential fatty acid that serves as metabolic precursor for eicosanoids and endocannabinoids.

Axon terminal Specialized structure of a neuron that secretes neurotransmitters.

G proteins Heterotrimeric proteins with GTPase activity that link the occupation of certain cell surface receptors to cellular responses.

Neurotransmitter Substance secreted by a neuron at a synapse.

Phospholipase A group of enzymes that catalyze the hydrolysis of phospholipids at their glycerol ester (PLA) of phosphodiester (PLC, PLD) bonds.

Protein kinase Enzyme that transfers a phosphate group from adenosine triphosphate to a protein.

Stereospecific numbering (sn) A convention on how to designate the stereochemistry of glycerol-based lipids. When the glycerol moiety is drawn with the secondary hydroxyl to the left, the carbons are numbered 1,2,3 from top to bottom.

Striatum A subcortical brain structure involved in the control of movement, habit learning, and the rewarding properties of drugs of abuse.

Synapse Specialized junction between the ending of the presynaptic neuron and the dendrite, cell body, or axon of a postsynaptic neuron.

Vanilloid receptor A receptor channel permeable to monovalent cations and activated by heat, acid, and capsaicin, the active ingredient of chili peppers.

The endocannabinoids are a family of biologically active lipids that bind to and activate cannabinoid receptors, the G-protein-coupled receptors targeted by Δ^9 -tetrahydrocannabinol in marijuana. The term encompasses several derivatives of arachidonic acid, which are generated on demand by neurons and other cells in response to physiological or pathological stimuli. The two best-characterized endocannabinoids are anandamide (arachidonylethanolamide) and 2-arachidonoylglycerol (2-AG). Others are noladin ether (2-arachidonoyl glyceryl ether) and virodhamine (O-arachidonoyl ethanolamine).

Synthesis

Anandamide

Anandamide is produced from the hydrolysis of an N-acylated species of phosphatidylethanolamine (PE), called N-arachidonoyl-PE. This reaction is initiated by activating neurotransmitter receptors and/or by elevating intracellular levels of Ca^{2+} ions and is probably catalyzed by phospholipase D. The anandamide precursor, N-arachidonoyl-PE, is present at low levels in nonstimulated cells, but its formation can be stimulated by Ca^{2+} and occurs simultaneously with that of anandamide. N-Arachidonoyl-PE synthesis is catalyzed by membrane-bound N-acyltransferase, which has been partially purified (see [Figures 1](#) and [2](#)).

2-Arachidonoylglycerol

In brain neurons, 2-AG formation is probably initiated by the activation of phospholipase C, which cleaves membrane phospholipids (e.g., phosphatidylinositol-4,5-bisphosphate) at the proximal phosphate ester bond, producing 1,2-diacylglycerol.

This intermediate is broken down by diacylglycerol lipase to yield 2-AG and free fatty acid. Another pathway of 2-AG release might involve the hydrolytic cleavage of a phospholipid at the *sn*-1 position of the glycerol backbone, catalyzed by phospholipase A_1 . This reaction yields a *sn*-2 lysophospholipid, which can be further hydrolyzed to produce 2-AG ([Figure 3](#)). Finally, 2-AG might be formed by hormone-sensitive lipase acting on triacylglycerols or by lipid phosphatases acting on lysophosphatidic acid. However, as these enzymes preferentially target lipids enriched in saturated or monounsaturated fatty acids, they are unlikely to play a role in the synthesis of a polyunsaturated species such as 2-AG.

Physiological Regulation of Endocannabinoid Synthesis

Anandamide

Anandamide synthesis is initiated by intracellular Ca^{2+} rises and/or by activation of G-protein-coupled receptors. For example, activation of vanilloid receptors elevates intracellular Ca^{2+} levels and stimulates anandamide synthesis in rat sensory neurons in culture. In addition, activation of dopamine D_2 -receptors enhances anandamide release in the brain striatum of the rat *in vivo*. The molecular steps involved in these effects have not yet been clarified.

2-Arachidonoylglycerol

2-AG formation is also linked to intracellular Ca^{2+} rises. For example, in freshly dissected slices of rat hippocampus, electrical stimulation of the Schaffer collaterals (a glutamatergic fiber tract that projects from CA3 to CA1 neurons) produces a

Figure 1 Chemical structures of the endocannabinoids anandamide (arachidonylethanolamide), 2-arachidonoylglycerol (2-AG), noladin ether, and virodhamine.

Figure 2 Anandamide biosynthesis. PE, phosphatidylethanolamine.

fourfold increase in 2-AG levels, which is prevented by the Na^+ channel blocker tetrodotoxin or by removing Ca^{2+} from the medium. It is notable that anandamide levels are not changed by the stimulation, suggesting that the syntheses of 2-AG and anandamide can be independently regulated. This idea is supported by the fact that activation of D_2 receptors, a potent stimulus for anandamide release in the rat striatum, has no effect on striatal 2-AG levels.

Deactivation

In the brain and other tissues, anandamide and 2-AG are rapidly eliminated through a two-step process consisting of

Figure 3 2-AG biosynthesis. 1,2-DAG, 1,2-diacylglycerol; DGL, diacylglycerol lipase; PL, phospholipase.

uptake into cells and enzymatic hydrolysis. The two endocannabinoids share a functionally similar transport mechanism, but they follow distinct routes of intracellular degradation.

Transport into Cells

The transport of anandamide and 2-AG into neurons and astrocytes is structurally specific, displays classical saturation kinetics, and is selectively inhibited by compounds such as *N*-(4-hydroxyphenyl)-arachidonamide (AM404). The putative transporter involved has not yet been identified, but transport has been shown to be Na^+ independent, which is suggestive of a facilitated diffusion mechanism.

Intracellular Hydrolysis

Inside cells, anandamide is metabolized by fatty acid amide hydrolase, a membrane-bound intracellular serine hydrolase that also cleaves oleoylethanolamide, an endogenous satiety factor, and other lipid amides. Hydrolysis of 2-AG is catalyzed instead by monoglyceride lipase, a cytosolic serine hydrolase that converts 2- and 1-monoglycerides into fatty acid and glycerol. The contribution of other lipases to 2-AG degradation cannot be excluded at present.

Cannabinoid Receptors

The endocannabinoids regulate the function of multiple organs and tissues of the body. These regulatory effects are primarily mediated by two G-protein-coupled receptors: CB_1 and CB_2 . CB_1 is highly expressed in the central nervous system, but is also present at lower levels in a variety of peripheral

tissues. By contrast, CB₂ is mostly found in immune cells such as lymphocytes. Both subtypes are linked to G_i/G_o proteins and can initiate signaling events typical of these transducing proteins, which include inhibition of adenylyl cyclase activity, opening of K⁺ channels, closing of Ca²⁺ channels, and stimulation of protein kinase activities. Nevertheless, CB₁ and CB₂ are structurally different (they have only 44% sequence homology), which has allowed the development of subtype-selective ligands such as the CB₁ antagonist SR141716A (rimonabant) and the CB₂ antagonist SR144528. There is evidence for the existence of at least two additional cannabinoid-sensitive sites in the brain and vasculature, which remain however uncharacterized.

Functions

In broad terms, the endocannabinoids are considered paracrine mediators, substances that act on cells near their sites of synthesis without entering the bloodstream. For example, they are formed by circulating leukocytes and platelets during hypotensive shock and induce the vascular relaxation that accompanies this phenomenon by activating CB₁ receptors on the surface of smooth muscle cells. Similar paracrine actions occur

in the brain, where the endocannabinoids mediate a localized signaling mechanism through which neurons modify the strength of incoming inputs. The endocannabinoids are generated by neuronal depolarization and travel backward across the synapse to regulate the release of neurotransmitters from neighboring axon terminals, a process called 'retrograde signaling'.

Glossary

Caveolae Flask-shaped invaginations from the plasma membrane that are enriched in cholesterol and glycosphingolipids and are coated with the protein caveolin.

Clathrin Cytosolic protein that polymerizes into basket-like coat complex on membranes, facilitating deformation of the plasma membrane to form a vesicle.

Dynamin GTP-binding protein that assembles at the necks of forming vesicles and facilitates the fission of membranes to release the vesicle.

Phagocytosis Endocytic process involving particle ingestion through extension of cell-surface membranes around particle (typically >250 nm in diameter) and membrane fusion to form phagosome.

Pinocytosis Endocytic process involving invaginations of the plasma membrane to generate small (100 nm in diameter) intracellular vesicles.

Endocytosis is a process carried out by all eukaryotic cells that involves the invagination of the cell-surface membrane and constricted closure to form a vesicle that enters the cell interior. Included in the internalized vesicle are extracellular fluid and plasma-membrane proteins and lipids. Endocytosis enables the cell to take up extracellular nutrients, remove activated receptors from the cell surface, and turn over cell-surface proteins and lipids. Endocytosis is also used for the removal of extracellular debris such as dead cells and bacteria, and as a cellular port of entry for infectious bacteria and viruses. Endocytosis can be broadly divided into pinocytosis (cell drinking) and phagocytosis (cell eating) (Figure 1). There are several types of pinocytosis. The best-characterized type is that involving endocytosis of vesicles coated on the cytoplasmic surface with a protein called clathrin. Phagocytosis involves ingestion of particles by extension and wrapping of the plasma membrane around the particle, bringing it into the cell. After internalization, the endocytosed material meets different fates: degradation, recycling back to the cell surface, or routing to other destinations within the cell.

Clathrin-Mediated Endocytosis

Endocytosis that is associated with clathrin coating enables certain plasma-membrane proteins to be concentrated and efficiently internalized (Figure 1(a)). The transferrin receptor and low-density lipoprotein (LDL) receptor are cell-surface proteins that are internalized by this mechanism, carrying iron-loaded transferrin protein and cholesterol-bearing LDL particles bound to these receptors into the cell. The clathrin coat that assembles on these structures forms a distinctive basket-like structure that can be visualized by electron microscopy. The polymerization of the clathrin coat is believed to facilitate changes in membrane curvature, deformation of the surface membrane, and formation of the vesicle. Once the vesicle has separated from the cell surface (fission), the clathrin coat is rapidly shed and then reutilized

for additional endocytic events. Clathrin-coated pits cover 2% of the plasma membrane and since they are believed to have a lifetime of ~1 min, ~2% of the cell-surface membrane is internalized each minute in the average cell. Clathrin-mediated endocytosis accounts for the bulk of pinocytosis in most cells. Clathrin assembly onto membrane requires the prior binding of a set of cytosolic adaptor proteins onto the plasma membrane.

Adaptor Proteins

The clathrin adaptor protein 2 complex (AP2) is composed of four different cytosolic proteins that bind to specific lipids and proteins at the plasma membrane and to clathrin, thus initiating clathrin assembly at distinct sites along the cell surface. There are three additional AP complex proteins in cells that associate with other cellular membranes, such as the Golgi complex, where they also facilitate clathrin assembly. One of the subunits of AP2 specifically binds to tyrosine-based, amino-acid sorting signals in the cytoplasmic regions of plasma-membrane proteins. The transferrin receptor contains such a tyrosine signal that sorts it into forming clathrin-coated PM vesicles, enabling the transferrin receptor to be efficiently and rapidly internalized into cells. In addition, there are other clathrin adaptor proteins that function at the PM, including disabled 2 (Dab2), and the autosomal recessive hypercholesterolemia protein (ARH), which is involved in the internalization of the LDL receptor. The ability to concentrate specific surface cargo proteins into clathrin-coated pits is the hallmark of clathrin-mediated endocytosis (Figure 2). There are other aminoacid sorting signals that allow for rapid internalization via clathrin endocytosis, including paired leucine and/or isoleucine residues. Plasma-membrane proteins that contain these sorting sequences are continually brought into cells by clathrin-mediated endocytosis. Some hormone receptors such as the β 2-adrenergic receptor lack these sorting sequences and do not appreciably enter clathrin-coated vesicles in the absence of hormonal stimulation. However, when the receptor is activated

Figure 1 Types of endocytosis. Features of the various types of endocytosis (pinocytosis and phagocytosis) are shown. (a) Clathrin-mediated pinocytosis is associated with a cytosolic coat of clathrin (X) and uses dynamin (black spots) for vesicle fission. (b) Caveolae are flask-shaped structures coated with caveolin that also use dynamin for vesicle fission. (c) Noncoated pinocytosis involves invagination of membrane that does not have a recognizable protein coat. (d) Macropinocytosis is associated with cell-surface actin-dependent protrusions and forms by fusion of the protruding membrane back onto the cell surface. (e) Phagocytosis is a process that is stimulated by an extracellular particle that induces actin-dependent cell extensions to envelope the particle.

Figure 2 Itinerary of internalized cell-surface receptors and vesicle contents. Shown here is the pathway followed by internalized LDL bound to the LDL receptor. Cell-surface LDL receptor binds to LDL and is sorted into forming clathrin-coated vesicles at the plasma membrane. After vesicle fission, the clathrin coat is rapidly released from the vesicle so it can assemble again onto the plasma membrane. The vesicle membrane then fuses with the early endosome, a membrane compartment that serves as a sorting station for membrane proteins and lipids. The low pH of the early endosome causes release of LDL from its receptor. The LDL particle and other molecules present in the fluid portion of the early endosome can then be routed to lysosomes for degradation. The LDL receptor enters regions of the early endosome that break off and carry these receptors and membrane back to the plasma membrane. Some membrane proteins leave the early endosome and are transported to other regions of the plasma membrane (transcytosis) or to the Golgi complex.

by a hormone, a special adaptor protein called β -arrestin binds to the receptor, allowing the receptor–arrestin complex to associate with AP2 and be rapidly internalized by the clathrin-dependent pathway.

Dynamin

The final step in endocytosis is membrane fission that allows the vesicle to detach from the cell surface. A guanosine triphosphate (GTP)-binding protein called dynamin facilitates this

process by assembling into ring-like structures and constricting at the necks forming clathrin-coated vesicles. Mutations in dynamin, originally described for *Drosophila melanogaster* mutants, freeze clathrin-forming vesicles at the constricted state and the vesicles are not released. All clathrin-mediated and some other types of endocytosis are dependent upon the function of dynamin. Dynamin also associates with other factors that may facilitate the fission process. Rearrangements in membrane lipids and changes in lipid composition also contribute to the changes in membrane curvature required for vesicle budding and vesicle fission.

Clathrin-Independent Endocytosis

Several other types of pinocytosis have been identified that are not associated with clathrin coats. We know little about the mechanisms of these processes and how they are regulated. Plasma-membrane proteins that lack the cytoplasmic amino-acid sequences specifying association with adaptor proteins and clathrin can be endocytosed into cells by these processes.

Caveolae

Some proteins associate with cholesterol and glycosphingolipid-enriched regions of the plasma membrane referred to as membrane raft domains. In many cells, especially in endothelial cells that line blood vessels, these raft domains are present in flask-shaped invaginations of the plasma membrane. These flask-shaped invaginations are called caveolae (caves), and the cytoplasmic coat protein associated with these structures that give them their distinctive shape is called caveolin (Figure 1(b)). Caveolar endocytosis is dependent upon dynamin and is used as an endocytic mechanism for the transport of materials across endothelial cells. Interestingly, simian virus 40 stimulates caveolar endocytosis and enters many types of cells through this mechanism. Finally, there are cells that lack caveolin and, hence, caveolae and yet endocytose proteins that associate with membrane raft domains.

Noncoated Endocytosis and Macropinocytosis

Plasma-membrane proteins and lipids are also observed in invaginations budding from the membrane that lack any identifiable protein coat (Figure 1). This process may or may not require dynamin function depending upon the cell type. This type of endocytosis is only beginning to be studied. Although this process may account for a smaller fraction of cell-surface endocytosis than clathrin-mediated endocytosis, it can be greatly stimulated when cells become activated and form membrane ruffles and protrusive structures. In this case, the membrane ruffle can fuse with the plasma membrane forming a large macropinosome that internalizes a large amount of surrounding fluid. Dendritic cells of the immune system are very active in macropinocytosis as a means of sampling foreign material in the extracellular fluid. Macropinosome formation is actin dependent. Some bacteria, notably *Salmonella typhi*, stimulate host cells to form membrane ruffles and macropinosomes, and then use these structures as a port of entry into the cells.

Phagocytosis

In lower eukaryotes, such as protozoa, this process of particle ingestion is used for nutrient uptake. However, in mammals, phagocytosis is observed in specialized cell types, namely, macrophages and neutrophils that ingest bacteria and dead cells and degrade them. When a macrophage encounters a bacterium that has been coated with antibodies generated by the immune system, cell-surface receptors that recognize the Fc portion of the antibodies are activated. This stimulates changes in the macrophage actin cytoskeleton and leads to the extension of membrane around the bacteria, and final closure of the structure through membrane fusion (Figure 1(e)). Macrophages are also active in phagocytosing senescent-red blood cells and other cells that have undergone programmed cell death. It is believed that macrophages can detect alterations on the cell surface of the senescent cell, such as appearance of a phospholipid on the outer surface that is normally present only on the cytoplasmic side of the plasma membrane. After phagocytosis, the resulting phagosome usually fuses with lysosomes and membrane-bound organelles that contain hydrolytic enzymes that degrade the bacteria. However, some bacteria such as *Mycobacterium tuberculosis* can actively prevent the fusion of the phagosome with lysosomal membranes, and hence escape degradation.

Fate of Internalized Membrane and Content

After endocytosis, the endocytic vesicle usually fuses with a membrane-bound structure called the early endosome (Figure 2). The early endosome accepts newly endocytosed material and serves as a sorting station that directs incoming proteins and lipids to their final destination. The early endosomal membrane contains a special membrane lipid, phosphatidylinositol 3-phosphate, which recruits cytosolic proteins onto these membranes and facilitates the fusion of incoming vesicles with the early endosome. The interior, luminal environment of the early endosome is moderately acidic (pH 6.5–6.0). The low pH facilitates the sorting process, releasing bound proteins

from their receptors and sorting membrane proteins and lipids into different domains. A good example of how low pH serves this function is the itinerary of the transferrin receptor that carries iron-saturated transferrin into the cell. The acidic environment of the early endosome causes the release of iron from transferrin. The iron is then transferred across the membrane into the cytosol, while the transferrin bound to the transferrin receptor is recycled back to the cell surface via membrane carriers that are released from the early endosome. Another example of this sorting of incoming material is the fate of internalized LDL particles bound to the LDL receptor (shown in Figure 2). LDL is released from the receptor in the early endosome and is transferred with other luminal material to late endosomes and lysosomes. There the LDL is degraded, causing cholesterol release inside the cell. Meanwhile, the LDL receptor returns to the cell surface to carry out additional rounds of endocytosis. For the transferrin and LDL receptors, endocytosis is a mechanism for the delivery of iron and LDL into the cell. By contrast, for signaling receptors, such as those activated by hormones and growth factors, endocytosis is generally used to halt the signaling process by the removal of the receptor from the cell surface. However, recent observations suggest that some signaling receptors, such as the epidermal growth factor receptor, require endocytosis for certain signaling activities.

Endocytosed membrane proteins can be transported to different locations in the cell (Figure 2). Some membrane proteins are sorted into vesicles that fuse to another region of the plasma membrane, a process called transcytosis. Mucosal immunoglobulins such as IgA are transcytosed across intestinal epithelia via IgA receptors that ferry IgA from the basal (serosal) side to the apical (mucosal) surface of the epithelia. Other proteins leave the early endosome in vesicles that fuse with membranes adjacent to the *trans*-Golgi complex.

Regardless of how a membrane is brought into the cell, it must be balanced by the addition of membrane back to the plasma membrane. This is accomplished by endosomal-membrane recycling and also through the contribution of newly synthesized membranes from the secretory pathway. The cell has to regulate and coordinate the flux of membrane into and out of the cell to maintain cell-surface area and for proper localization of important cell-surface receptors.

Glossary

Calnexin and calreticulin Calnexin is a nonglycosylated type I protein of the endoplasmic reticular (ER) membrane with 573 amino acids. Most of them are present in the lumen of the ER and comprise a glucose-binding site for transient association with folding substrates and a P-domain for noncovalent association with the co-chaperone ERp57; 89 residues are cytosolic and contain a RKPRRE ER-retention sequence. Calreticulin is the soluble homolog of calnexin; it has 400 amino acids with a KDEL (Lys–Asp–Glu–Leu) ER-retrieval sequence.

EDEM proteins EDEM1 (for ER degradation enhancing alpha mannosidase-like protein), EDEM2, and EDEM3 are ER-resident soluble glycoproteins involved in the disposal of misfolded polypeptides from the ER lumen. They belong to the glycosyl hydrolase 47 (GH47) family. Their intracellular level increases in response to accumulation of misfolded proteins in the ER lumen. Some controversy exists as to

their function in the ER lumen. In particular, it is disputed if they are mannose-binding lectins or mannose-processing enzymes. So far, it has been demonstrated that at least EDEM1 is an active mannosidase.

ERAD ER-associated protein degradation collectively describes the processes leading to recognition of misfolded proteins present in the ER lumen and their dislocation into the cytosolic compartment for proteasome-mediated destruction.

Lectin Lectins are carbohydrate-binding proteins, which are often classified based on their binding specificity. They are involved in many biological processes, including polypeptide folding, transport, and ERAD.

Quality control It describes the capacity of cells to distinguish and retain in the ER lumen, to be eventually targeted for degradation, proteins that have structural defects.

For proper functioning, a protein has to fold into a characteristic three-dimensional structure and may have to form a multimeric complex. The endoplasmic reticulum (ER) provides an environment optimized for the folding and assembly of proteins that will then be either secreted (hormones, antibodies, pancreatic enzymes, etc.) or displayed at the plasma membrane (receptors, channels, etc.), or that reside in intracellular compartments, such as the lysosomes and the Golgi. Only native proteins leave the ER to be transported along the secretory pathway to their final destination. A quality-control system is in place to prevent forward transport of polypeptides for which folding and assembly have failed. To prevent their accumulation in the lumen of the ER, terminally misfolded polypeptides are dislocated into the cytosol to be degraded by 26S proteasomes. This occurs in a series of events collectively named 'ER-associated protein degradation (ERAD)'. This process is regulated by luminal, membrane-embedded, and cytosolic components that interrupt futile folding attempts, direct misfolded proteins at specific sites in the ER membrane, facilitate their dislocation across the membrane, and insure polyubiquitylation that facilitates extraction from the ER and proteasomal intervention. The aim of this article is to summarize recent advances in understanding how misfolded glycoproteins are cleared from the ER lumen of mammalian cells.

Protein Synthesis and Folding in the ER

In mammalian cells, secretory proteins are synthesized by ribosomes associated at the cytosolic face of the ER at an average

rate of 3–5 amino acids per second. Nascent chains are translocated into the ER lumen and most of them become N-glycosylated upon addition of pre-assembled, branched oligosaccharides (N-glycans) at asparagines in Asn–Xaa–Ser/Thr sequons. The highly hydrophilic N-glycans preserve the solubility of yet unstructured chains likely to expose hydrophobic, aggregation-prone patches. Most importantly, they act as ligands for calnexin and calreticulin, two lectin chaperones that make nascent chains accessible to ERp57. ERp57 is an oxidoreductase that catalyzes the formation of disulfide bonds, a rate-limiting step of the folding process peculiar for proteins expressed in the ER. As thoroughly reviewed elsewhere (see section Further Reading), calnexin, calreticulin, and ERp57, together with the sugar-processing enzymes glucosidase I and II and uridine diphosphate (UDP)-glucose:glycoprotein glucosyltransferase (GT) compose the calnexin/calreticulin cycle, a chaperone network that assists folding and quality control of glycoproteins.

The kinetics and the efficiency of the folding process are highly variable and depend on the substrate–protein considered and on the cell type where folding occurs. Somewhat surprisingly, the folding of heterologous proteins might be faster and significantly more efficient compared to the maturation of cell self-proteins. Hence, it may take only 10 min for a viral glycoprotein (e.g., influenza virus hemagglutinin) to complete the folding and oligomerization processes and to leave the ER with an efficiency approaching 100%. On the other hand, it may take several hours before roughly 20% of the cystic fibrosis transmembrane conductance regulator (CFTR) expressed in the ER lumen becomes native and leaves the compartment for the cell surface. About 80% of the wild-type

CFTR never attains the native structure and is degraded shortly after synthesis. A relatively low folding efficiency is a common feature for several eukaryotic gene products and has no consequences. However, folding efficiency and transport of the polypeptide at the site of activity may drop substantially, and can be the cause of impaired cell, organ, and/or organism viability when genetic mutations occur that change or delete amino acids. If the mutated protein cannot fold properly, it will not fulfill the quality-control standard for ER exit and will eventually become a substrate of the ERAD machinery or will accumulate intracellularly in toxic aggregates. For example, deletion of phenylalanine at position 508 of CFTR (Δ Phe508 CFTR) results in 99% of the protein being incapable of attaining the native structure. This results in a loss-of-function disease (cystic fibrosis) caused by the absence of functional CFTR at the cell surface.

Protein disposal from the ER also plays an important regulatory role, as exemplified by hydroxymethylglutaryl (HMG)-CoA reductase, a rate-limiting enzyme for the production of sterols and a variety of essential isoprenoids, whose intracellular level is controlled, at least partially, by regulated degradation.

Diseases Related to Failure of Protein Folding and Quality Control in the ER

An increasing number of strongly debilitating human diseases have been ascribed to defective protein folding and quality control. Together with cystic fibrosis, one could mention the hereditary lung emphysema and liver failure caused by α 1-antitrypsin deficiency, diabetes mellitus caused by retention and degradation from the ER of mutant insulin receptors, familial hypercholesterolemia (low-density lipoprotein receptor), osteogenesis imperfecta (type I procollagen), retinitis pigmentosa, and several neurodegenerative diseases. In these so-called 'conformational diseases', mutated proteins that do not acquire their native structure are retained in the ER and are diverted to ERAD. If their disposal is not efficient, they accumulate intra- or extracellularly, triggering severe damages to cells and tissues. In some cases, such as the hereditary lung emphysema caused by α 1-antitrypsin deficiency (α 1-antitrypsin is the principal blood-borne inhibitor of the destructive neutrophil elastase in the lungs), the lack-of-function phenotype observed at the level of patient's lungs is accompanied by a gain-of-toxic-function phenotype at the level of the patient's liver because the mutated protein accumulates in the ER of hepatocytes.

Degradation of Aberrant Proteins Expressed in the ER: The Mannose Timer

How are polypeptides recognized as being misfolded, retained in the ER, and targeted for ERAD? First, it has to be mentioned that the quality-control machinery of the ER checks the structure and not the function of newly synthesized proteins. Therefore, function-competent proteins can be retained in the ER and destroyed because they are structurally imperfect. This is the case, as one example, of the Δ Phe508 CFTR.

Second, modification of protein-bound oligosaccharides determines the fate of newly synthesized glycoproteins within

the ER. N-Glycans are added as pre-assembled units composed of two *N*-acetyl-glucosamine, nine mannose, and three glucose residues. The ER-resident glucosidase I and glucosidase II sequentially remove the two outermost glucose residues in a matter of seconds after addition of the N-glycan to nascent polypeptide chains. In the minutes following the synthesis of a glycoprotein, the number of glucose residues on N-glycans can vary from 0 to 1 in response to the counteracting enzymatic activities of glucosidase II and GT. These modifications control cycles of dissociation from/association with the lectin chaperones calnexin and calreticulin. How long newly synthesized proteins are retained in the calnexin/calreticulin cycle depends on their rate of folding. As GT recognizes only pseudo-native structure, immature polypeptides are repeatedly re-glucosylated and retained in the calnexin/calreticulin cycle, whereas native glycoproteins exit the folding cycle, leave the ER, and are secreted.

In this model, proteins unable to fold properly persist in the calnexin/calreticulin cycle. To prevent accumulation of aberrant polypeptides in the ER, terminally misfolded polypeptides have to be released from the calnexin/calreticulin cycle and to be targeted for disposal and degradation. After several unsuccessful folding attempts, N-glycans become substrates of several slow-acting ER-resident mannosidases. Therefore, long retention in the ER as signaled by a reduced number of mannose residues on N-glycans is a clear symptom of a problematic folding. It was originally proposed by Helenius in 1994 that a timer based on mannose cleavage exists in the ER that decides when it is time to stop folding attempts and to direct folding-defective polypeptides for degradation. The involvement of mannosidases in ERAD is supported by findings showing that cleavage of mannose residues from N-glycans facilitates extraction of misfolded polypeptides from the calnexin/calreticulin cycle and is essential for disposal of misfolded polypeptides.

ER-Resident α 1,2-Mannosidases

In mammalian cells, extensive de-mannosylation is performed by one or more members of the glycosyl hydrolase family 47 (GH47) of α 1,2 mannosidases. This family comprises the ERManI, EDEM (ER degradation enhancing α mannosidase-like protein) family members (EDEM1-3), and a collection of Golgi-resident enzymes. Recent models claim that ERManI removes the terminal mannose from the middle branch of N-glycans and EDEM proteins (at least EDEM1 and EDEM3) further process the oligosaccharide to eventually generate a Man₅₋₆ structure that does not support binding to the folding lectins calnexin and calreticulin anymore. Misfolded polypeptides displaying de-mannosylated oligosaccharides are therefore extracted from the folding machinery and redirected into the disposal machinery.

Distinct ER Chaperone Networks Are Involved in the ERAD Process

Involvement of at least two distinct chaperone networks, the calnexin/calreticulin cycle and the BiP/protein disulfide isomerase (BiP/PDI) system, has been shown to regulate degradation of ERAD candidates in mammalian cells. Interestingly, misfolded glycoproteins remain in the calnexin/calreticulin

Figure 1 The ERAD mechanism as depicted in this figure can be divided into four steps: first, the folding-incompetent glycoprotein is extracted from the calnexin cycle through the concerted activity of several mannose-trimming enzymes (GH47); second, the lectin ERAD shuttles OS-9 and XTP3-B transport the misfolded glycoprotein from the ER lumen to the membrane-anchored adaptor protein SEL1L, which is associated with the E3 ubiquitin ligase HRD1; third, the misfolded glycoprotein has to be unfolded (e.g., reduction of aberrant disulfide bonds and *cis/trans* isomerization of peptidyl–prolyl bonds) in order to; and fourth, allow dislocation across the ER membrane through an elusive channel, polyubiquitylation and degradation by the 26S proteasome. The different mannose composition of the N-glycan is depicted in color code: gray, oligosaccharide with nine mannose residues (Man₉); red, five to seven mannose residues (Man₅₋₇); and white, oligosaccharide with an undefined number of mannose residues.

cycle when degradation is blocked by mannosidase inhibitors, whereas they are released from the lectin chaperones to remain trapped in the BiP/PDI system when the proteasome activity is specifically inhibited. These data show that the two chaperone networks work sequentially and offer the appealing view that ERAD candidates are first subjected to folding attempts in the calnexin/calreticulin cycle (lag between synthesis and degradation onset) to be then transferred to the BiP/PDI system that would regulate unfolding and dislocation of the aberrant polypeptide into the cytosol for proteasome-mediated degradation.

ERAD Receptors: The Mannose-Binding Lectins

It has been recently shown by the groups of Markus Aebl and Jon Weissman that substrate de-mannosylation generates a signal for disposal. In fact, de-mannosylated oligosaccharides on ERAD substrates expose terminal α 1,6-bonded mannose residues. These recruit a series of ERAD lectins containing mannose 6-phosphate receptor homology domains (MRH), namely the OS-9 and the XTP3-B splice variants. OS-9 and XTP3-B are stress-inducible genes whose expression is regulated by the ER-stress-activated transcription factor Xbp1. They play a crucial role in retention-based ER quality control and ERAD. Current models propose that OS-9 and XTP3-B, as

well as other ER chaperones, such as BiP, GRP94, and PDI, shuttle misfolded polypeptides from the ER lumen to retrotranslocation (dislocation) complexes in the ER membrane. They deliver the misfolded polypeptides to the transmembrane protein SEL1L, which is associated with HRD1, a membrane-embedded E3 ubiquitin ligase. Dislocons also contain an elusive proteinaceous pore that serves as the conduit for the dislocation of ERAD substrates to the cytoplasm (see Figure 1). The identity of the actual channel remains controversial as a number of ER membrane proteins have been proposed to serve this function including Sec61, Derlins, and E3 ubiquitin ligases themselves.

Glossary

ATP synthase (F_0F_1 -ATPase) An enzyme in mitochondria and bacteria for the phosphorylation of adenosine diphosphate (ADP), which is driven by the proton potential over the membrane.

Chemiosmotic hypothesis Mechanisms for the coupling of the endergonic adenosine triphosphate (ATP) synthesis by ATP synthase to the exergonic electron transport via a proton potential over the membrane.

Denitrification A form of nitrate respiration that is performed by bacteria in soil and water such as *Paracoccus* and *Pseudomonas* strains, resulting in the formation of N_2 as the product (nitrite, NO, and N_2O as the intermediates).

Nitrate ammonification A form of nitrate respiration producing ammonia as the end product (nitrite as the intermediate); typical for enteric bacteria such as *Escherichia coli*.

Oxygen sensors Facultatively anaerobic bacteria such as *E. coli* or *Pseudomonas* repress the synthesis of pathways for anaerobic respiration or fermentation by transcriptional regulators responding directly (e.g., fumarate nitrate reductase regulator FNR of *E. coli* with an O_2 -sensitive [4Fe4S] cluster) or indirectly to O_2 .

Prokaryotes Microorganisms, mostly unicellular, in which the chromosome is organized in a nucleoid (rather than a nucleus) which is not separated from the cytoplasm by a membrane. Bacteria and Archaea, two of the three major domains of living organisms, are prokaryotes.

Redox half-loop enzymes Enzymes or mechanism for H^+ potential formation that is common in anaerobic respiration (e.g., nitrate reductase, formate dehydrogenase, and hydrogenases). The H^+ potential is formed by the consumption and the release of H^+ on opposite sides of the membrane and e^- transfer (generally $2 H^+ / 2 e^-$) without direct H^+ translocation across the membrane.

Many prokaryotes (bacteria and archaea) are able to grow in the absence of molecular O_2 . Under anaerobic conditions, metabolic energy is gained by the catabolic reactions of fermentation, anaerobic respiration, anoxygenic photosynthesis, decarboxylation of dicarboxylic acids, or electrogenic transport of substrate and product molecules. Many of the reactions are unique for prokaryotes. Anaerobic metabolism is essential for biotopes, which are permanently or occasionally anoxic. The bacteria responsible for anaerobic metabolism and mineralization are strictly anaerobic and are restricted to anaerobic biotopes, or are facultatively anaerobic, using either aerobic or anaerobic metabolism, depending on the O_2 supply. The facultative bacteria switch between aerobic and anaerobic metabolism by using molecular O_2 sensors, which control the expression of aerobic or anaerobic metabolic systems mostly at the transcriptional level.

Adenosine Diphosphate Phosphorylation Driven by Chemical Coupling or by the Membrane Potential

Synthesis of adenosine triphosphate (ATP) by fermentation relies on substrate-level phosphorylation, whereas the other reactions for anaerobic energy conservation use a membrane potential as the coupling device between energy-supplying and energy-consuming reactions, in particular adenosine diphosphate (ADP) phosphorylation (Figure 1). Phosphorylation of ADP for generation of ATP requires a free energy ($\Delta G_0'$) of approximately $+50 \text{ kJ mol}^{-1}$, or higher, under cellular conditions. This amount of free energy has to be supplied in fermentation by direct coupling in one chemical reaction. In the metabolic systems using the membrane or proton potential

(Δp) as the coupling device (Figure 1), the energy-supplying reaction, on the other hand, has to supply only $12\text{--}17 \text{ kJ mol}^{-1}$ per reaction, which is the amount required for translocating one H^+ (or Na^+) ion across the membrane. Three or four H^+ ions are used then to drive ADP phosphorylation. Therefore, storing the free energy in a membrane potential is favorable for anaerobic catabolic processes, which often provide only small amounts of free energy.

The overview will demonstrate, by examples, the functioning of anaerobic metabolism of bacteria, in particular, fermentation, and reactions using a membrane potential for coupling between energy-supplying and energy-consuming reactions.

Fermentation

Fermentation plays a major role in the carbon cycle of anaerobic sediments in freshwater, sewage fermenters, or the digestive apparatus of vertebrates and insects. Fermentation means growth in the absence of external electron acceptors or light. ADP is phosphorylated under these conditions by substrate-level phosphorylation, or direct chemical coupling, without the involvement of membranes or membrane potential. The most common substrates for fermentative metabolism are sugars and amino acids. The substrates are first degraded in an oxidative part of metabolism yielding pyruvate or related compounds and reduced nicotinamide adenine dinucleotide (phosphate) (NAD(P)H). For oxidation of the sugars, most bacteria use the glycolytic (Embden–Meyerhof–Parnas, EMP) pathway to pyruvate ($\text{glucose} + 2\text{NAD}^+ + 2\text{ADP} + 2\text{P}_i \rightarrow 2\text{pyruvate} + 2\text{NADH} + 2\text{H}^+ + 2\text{ATP}$). Some bacteria use the phosphoketolase (modified pentosephosphate) pathway

(glucose + 3NAD(P)⁺ + ADP + P_i + HSCoA → pyruvate + acetyl-CoA + 3NADH + 3H⁺ + 1ATP) for pyruvate formation, whereas the Entner–Doudoroff (or 2-keto-3-deoxy-6-P-gluconate, KDPG) pathway (glucose + 2NAD(P)⁺ + ADP + P_i → 2pyruvate + 2NAD(P)H + 2H⁺ + 1ATP) is found only rarely in anaerobic bacteria.

In simple fermentations, pyruvate is used as the electron acceptor for reoxidation of the NAD(P)H formed during sugar oxidation, yielding lactate or ethanol as the fermentation products. In more complicated fermentation reactions (mixed acid fermentation, butyrate fermentation, and others), pyruvate is further oxidized yielding acetate and additional ATP. In these pathways, butyrate or ethanol (plus acetate) can be obtained as fermentation products, among others.

Typical fermentation products derived from sugars and amino acids are carboxylic acids (formate, acetate, propionate, butyrate, and lactate), alcohols (ethanol, 2-propanol, *n*-butanol, and 2,3-butanediol), but also polyols (glycerol, erythritol, and mannitol), CO₂, and H₂ (Table 1). The well-known fermentation reactions of this type are homo- and heterofermentative lactic acid, propionic acid, butyric acid, mixed acid, or ethanolic fermentations, which are named according to the major or characteristic products (Table 1). The ATP yields of the fermentation reactions are generally in the range of 1–3

ATP mol⁻¹ of hexose (compared to up to 38 ATP mol⁻¹ glucose in aerobic metabolism).

The most important energy-conserving reactions in fermentation are the oxidation of aldehyde to carbonates (thioester formation by glyceraldehyde-3-phosphate dehydrogenase), the oxidative decarboxylation of α-ketoacids (thioester formation by pyruvate-ferredoxin oxidoreductase), and the phosphoroklastic cleavage of ketuloses (acetyl-phosphate formation by phosphoketolase), which are all located in the oxidative part of fermentative metabolism. Reductive deamination of amino acids (acetyl-phosphate formation by glycine reductase) is an example of an energy-conserving reaction in the reductive branch of Stickland fermentation. The energy-rich products obtained from these reactions are then used finally for the phosphorylation of ADP, yielding ATP.

Organic matter (polysaccharides, proteins, fats, and monomers derived thereof) can be mineralized in the absence of external electron acceptors to methane and CO₂ by the interaction of fermenting and methanogenic prokaryotes in an anaerobic food chain (Figure 2). Primary fermenters degrade sugars and amino acids by typical fermentation reactions to propionate, butyrate, succinate, lactate, acetate, ethanol, CO₂, H₂, and NH₃. Ethanol and fatty acids (short-chain fatty acids, such as propionate, up to C₁₈) are then degraded by secondary fermenters to acetate, H₂, and CO₂. H₂, CO₂, and acetate from the former fermentation reactions are converted by homoacetogenic and methanogenic prokaryotes to methane and CO₂. Secondary fermentation is mostly an endergonic process under standard conditions (e.g., butyrate + 2H₂O → 2acetate + H⁺ + 2H₂; ΔG₀' = +48.2 kJ mol⁻¹ butyrate) and becomes exergonic only in the presence of syntrophic prokaryotes, which consume H₂ and other products to keep them at very low levels. By this, the reaction becomes exergonic under environmental conditions (ΔG_{env} = -18 kJ mol⁻¹ butyrate), enabling growth of the bacteria. In this way, fatty acids, alcohols, and aromatic compounds are mineralized yielding CO₂ and methane as the final products.

Fermentation reactions are used on a large scale for the preparation of food and beverages. The fermentation reactions and products improve food (nutritional) quality, taste, and durability. For this purpose, mainly primary fermentation reactions such as ethanol (beverages), lactic acid (dairy products, vegetables, and sour dough), propionic acid fermentations (cheese), and others are used. Solvent production (ethanol, propanol, butanol, and acetone) by Clostridia also depend on type I fermentations. Biotechnological processes for

Figure 1 Generation of a proton potential (Δp) by translocation of protons across a cytoplasmic membrane by anaerobic respiration and by coupling to ADP phosphorylation by ATP synthase. DH₂, electron donor; A, electron acceptor.

Table 1 Fermentation products of sugars (primary fermentations)

Fermentation (pathway for sugar degradation)	Products per mol glucose (ATP yield per glucose)	Bacterium or microorganism
Lactic acid, homofermentative (EMP)	2 Lactate (+2ATP)	<i>Lactobacillus lactis</i>
Lactic acid, heterofermentative (PK)	1 Lactate + 1 ethanol + 1CO ₂ (+1ATP)	<i>Leuconostoc</i>
Propionic acid (EMP)	2 Propionate (+2–3ATP)	<i>Propionibacterium</i>
Butyric acid (EMP)	1 Butyrate + 2CO ₂ + 2H ₂ (+3ATP)	<i>Clostridium butyricum</i>
Mixed acid (EMP)	1 Acetate + 1 ethanol + 2 formate (+3ATP)	<i>Escherichia coli</i>
Ethanolic (ED)	2 Ethanol + 2CO ₂ (+1ATP)	<i>Zymomonas mobilis</i>
Ethanolic (EMP)	2 Ethanol + 2CO ₂ (+2ATP)	<i>Saccharomyces cerevisiae</i> (yeast)

EMP, Embden–Meyerhof–Parnas pathway (glycolysis); PK, phosphoketolase pathway; ED, Entner–Doudoroff pathway.

Figure 2 Role of primary and secondary fermentation, and of methanogenesis in the anaerobic degradation of organic matter in the absence of electron acceptors. The food chain shown here is found in anaerobic sediments, sewage sludge, and the digestive apparatus of vertebrates and insects. Most reactions of secondary fermentation are endergonic under standard conditions, but become exergonic under environmental conditions ($\Delta G'_{\text{env}}$) when the levels of H_2 , CO_2 , and acetate are kept low by methanogenic archaea or by bacteria.

microbiological production of amino acids, citrate, and others, on the other hand, rely on an overflow metabolism of central pathways and anabolic reactions.

Electron Transport Phosphorylation in Anaerobic Respiration

Anaerobic respiration is able to generate an electrochemical proton potential ($\Delta p \sim -0.18 \text{ V}$) over the membrane, which is driven by the oxidation of an electron donor by an (mostly externally added) electron acceptor. The free energy of the redox reaction is conserved in a proton potential (Figure 1). The proton potential then drives phosphorylation of ADP and formation of ATP by ATP synthase. The Δp -generating respiratory chain and the Δp -consuming ATP synthase are thus coupled only by the Δp . The free energy of the redox reaction of the respiratory chain under standard conditions and pH 7 is directly related to the difference in the redox potentials of the electron donors and acceptors ($\Delta E'_0$), the Faraday constant ($F = 96.5 \times 10^3 \text{ J mol}^{-1} \text{ V}^{-1}$), and the number of participating electrons (n):

$$\Delta G'_0 = -nF\Delta E'_0$$

Figure 3 gives a selection of important electron donors and acceptors used by prokaryotes in anaerobic respiration and the corresponding midpoint potentials. The $\Delta E'_0$ value sets the maximal (theoretical) amount of electrons (H^+/e^- ratio),

which can be translocated across the membrane for the given Δp value (-0.18 V):

$$(\text{H}^+/\text{e}^-)_{\text{max}} = \Delta E'_0 / \Delta p$$

The actual H^+/e^- ratio generally is lower than the calculated value due to lower coupling efficiency, and since some electron transport enzymes lack coupling mechanisms for H^+ translocation. From the above equations, it follows that the minimal amount of free energy required for the translocation of one H^+ ion across membranes ($\Delta p = -180 \text{ mV}$) is $-17.4 \text{ kJ mol}^{-1}$. Thus, free energy as low as $\Delta G'_0 = -17 \text{ kJ mol}^{-1}$ can be conserved in a membrane potential by anaerobic respiration (or other Δp -generating reactions) compared to the $\Delta G'_0$ value of at least -50 kJ mol^{-1} required in substrate-level phosphorylation. Electron transport therefore allows use of energy-supplying reactions with low $\Delta G'_0$ values, since three to four translocated H^+ or Na^+ ions (derived from up to four energy-supplying reactions) are used for phosphorylation of one ADP molecule. This coupling mechanism is of particular significance for reactions of anaerobic metabolism, which are only weakly exergonic.

In anaerobic respiration, a large number of different electron acceptors can be used, including S^0 , CO_2 , sulfate, fumarate, nitrate, tetrachlorethen, and Fe^{3+} (Figure 3). The free energy, and thus the ATP yields, are distinctly lower than in aerobic respiration due to the more negative redox potentials (and thus $\Delta E'_0$ values) of the electron acceptors. Most of the anaerobic respiratory systems are composed of two enzymes, a dehydrogenase and a terminal reductase. The enzymes are linked by diffusible low-molecular-weight redox mediators (quinones). In anaerobic respiration, menaquinone (MK, a lipophilic naphthoquinone derivative with $E'_0 = -80 \text{ mV}$) replaces ubiquinone (Q, a lipophilic benzoquinone derivative with $E'_0 = +110 \text{ mV}$) from aerobic respiratory chains. Figure 4 gives a schematic presentation of the topology and arrangement of enzymes in fumarate and nitrate respiration, with formate as the electron donor. The biochemistry and energetics of the enzymes are known in detail, and the structures of the enzymes have been solved by X-ray crystallography. Each of the enzymes is anchored in the membrane by a hydrophobic anchor protein, which contains the active site for the lipophilic quinone. The second active site for the hydrophilic substrates, formate, fumarate, or nitrate, has either cytoplasmic or extracellular topology.

In formate–fumarate respiration, the enzymes catalyze the following reactions:

Formate dehydrogenase (or formate:quinone oxidoreductase):

Fumarate reductase (or menaquinol:fumarate reductase):

Formate–fumarate reduction:

The overall reaction of formate–fumarate respiration results in the release of two H^+ ions at the periplasmic, and consumption of two H^+ ions at the cytoplasmic side of the membrane

Figure 3 Important electron acceptors of anaerobic respiration by prokaryotes. The scheme gives the redox potentials of the redox pairs, the type of respiration, the metabolic balance using H_2 as the electron donor, and examples for prokaryotes catalyzing the reaction. The free energy of the reaction can be calculated from $\Delta G'_0 = -nF\Delta E'_0$, and is, for example, for fumarate respiration ($H_2 + \text{fumarate} \rightarrow \text{succinate}$) $\Delta G'_0 = -87 \text{ kJ mol}^{-1}$.

resulting in a $H^+/2e^-$ ratio of 2, which is caused by the action of formate dehydrogenase. Formate dehydrogenase has active sites for formate oxidation and menaquinone reduction on opposite sides of the membrane, and translocates two electrons from the formate to the quinone site, resulting in an overall translocation of two charges across the membrane. The enzyme releases and consumes H^+ ions on opposite sides of the membrane (without actual translocation of H^+), resulting in Δp production. Many anaerobic respiratory enzymes generate Δp in the same way. This mechanism of Δp generation by redox half-loop enzymes has to be distinguished from proton-pumping redox enzymes, such as cytochrome *c* oxidase, which transfer protons across the membrane in a reaction, which is driven by a redox reaction (proton pump).

In fumarate reductase, the protons are released (menaquinol site) and consumed (fumarate site) on the same (cytoplasmic) side of the membrane. The reaction, therefore, is not electrogenic and does not contribute to the formation of Δp , and fumarate reductase functions only as an electron sink. The overall $H^+/2e^-$ ratio of formate–fumarate reduction is 2. The big difference in the redox midpoint potentials of formate and menaquinone in formate:menaquinone reduction ($\Delta E'_0 = -340 \text{ mV}$) allows the generation of a proton potential ($H^+/2e^-$ ratio ≤ 3.8). For fumarate reductase, the $\Delta E'_0$ ($\Delta E'_0 = -110 \text{ mV}$) is not sufficient for generation of a proton

potential. Similarly, other terminal reductases of bacterial respiratory chains function without direct contribution to Δp production.

Formate–nitrate respiration is catalyzed by an electron transport chain consisting of formate dehydrogenase and nitrate reductase:

Formate dehydrogenase (or formate:quinone oxidoreductase):

Nitrate reductase (or quinol:nitrate reductase):

Formate–nitrate reduction:

In quinol–nitrate reduction, $\Delta E'_0$ is -510 mV with menaquinol, or -350 mV with ubiquinol as the electron donor, which allows conservation of the redox energy in a proton potential (Figure 4). Accordingly, nitrate reductase functions as a redox half-loop enzyme very similar to (though mirror-inverted) formate dehydrogenase. Overall, formate–nitrate respiration has a $H^+/2e^-$ ratio of 4.

A similar organization is found for many enzymes of anaerobic respiratory chains, which are composed of one respiratory

Figure 4 Formate–fumarate and formate–nitrate respiration. The figure shows the topology and reactions of formate dehydrogenase (formate: quinol reductase, Fdh), fumarate reductase (quinol:fumarate reductase, Frd), and nitrate reductase (quinol:nitrate reductase, Nar). Note the topology of the active sites for formate, fumarate, nitrate, and the quinones, the release and consumption of H^+ at the active sites, and transmembrane transfer of electrons in formate dehydrogenase and nitrate reductase. Frd, fumarate reductase; Nar, Nitrate reductase; Fdh, formate dehydrogenase. Examples of this type of fumarate respiration are found in *E. coli* and *Wolinella*, and of the nitrate respiration in *E. coli*. Formate dehydrogenase and nitrate reductase represent redox half-loop enzymes. The latter enzymes generate a proton potential by transfer of electrons across the membrane and by consuming and releasing protons on opposite sides of the membrane. Due to the topology of the substrate and quinone sites, a H^+ potential is produced without H^+ translocation.

dehydrogenase and terminal reductase each, and which are linked by the quinones. In this way, a large number of different respiratory dehydrogenases and terminal reductases can be connected in branched respiratory chains.

Decarboxylation of Dicarboxylic Acids

Some anaerobic bacteria grow at the expense of decarboxylation of dicarboxylic acids, such as oxaloacetate or succinate. The free energy of this reaction is $\sim -20 \text{ kJ mol}^{-1}$ and is used for translocation of one Na^+ ion across the membrane by a membranous decarboxylase as the energy-conserving enzyme. The sodium motive force generated in this way is used to drive secondary substrate transport, flagella, motility, or phosphorylation of ADP, if the bacteria contain an Na^+ potential-driven ATP synthase. The Na^+ -dependent ATP synthase is similar in function and composition to the H^+ -translocating F_1F_0 -ATP synthase. In this way, three to four decarboxylation reactions are required for phosphorylation of one ADP molecule. *Propionigenium modestum* grows by conversion of succinate to

Figure 5 Anaerobic growth on succinate by *P. modestum* (succinate + $H_2O \rightarrow$ propionate + CO_2 ; $\Delta G_0' = -21 \text{ kJ mol}^{-1}$) and generation of an Na^+ potential by decarboxylation. The membranous methylmalonyl-CoA decarboxylase couples decarboxylation to translocation of two Na^+ ions over the membrane. H^+ ions for the decarboxylation reaction are derived from the outside.

propionate, including decarboxylation of methylmalonyl-CoA by a membranous decarboxylase (Figure 5). Succinate is converted to methylmalonyl-CoA, which is then decarboxylated in a reaction coupled to Na^+ ion translocation. The enzyme, in addition, consumes one H^+ ion from the periplasmic side of the membrane for the formation of propionyl-CoA and CO_2 . Thus, the free energy of decarboxylation is used for generating an electrochemical Na^+ potential. The decarboxylation represents an intramolecular redox reaction producing an oxidized (CO_2) and a reduced (propionate) product. The reaction depends only on the membranous decarboxylase for generation of the electrochemical potential. In *Klebsiella*, an enterobacterium closely related to *Escherichia coli*, a membranous Na^+ translocating decarboxylase (oxaloacetate decarboxylase), is part of citrate fermentation. Oxaloacetate decarboxylation yields pyruvate, which can be further converted to acetate and formate. In citrate fermentation, ATP is formed in addition by substrate-level phosphorylation, or a H^+ potential is generated in respiratory pathways. Therefore, the ATP synthase of *Klebsiella* is H^+ -ion dependent, and the Na^+ potential is used mainly for secondary substrate transport.

Generation of an H^+ Potential by Transport of Charged Substrate and Product Molecules

Some bacteria use the (electrogenic) transport of substrate and product molecules for the generation of a proton potential. *Oxalobacter formigenes* and lactic acid bacteria such as *Lactococcus lactis* or *Oenococcus oeni* are able to generate a proton potential by decarboxylation of the dicarboxylic acids oxalate or malate. The decarboxylation is catalyzed by cytoplasmic

Figure 6 Anaerobic growth on oxalate by *Oxalobacter formigenes* (oxalate $\rightarrow$ formate + CO_2 ; $\Delta G_0' = -27 \text{ kJ mol}^{-1}$) and generation of a H^+ potential by electrogenic oxalate $^{2-}$ /formate $^{1-}$ antiport and decarboxylation of oxalate by a cytoplasmic (H^+ -consuming) decarboxylase.

enzymes, and the free energy of the reaction is not directly stored in a membrane potential as in the membranous decarboxylases. In *Oxalobacter*, oxalate is taken up by an electrogenic antiporter with formate, the end product of the pathway (Figure 6). Decarboxylation of activated oxalate (oxalyl-CoA) produces CO_2 and consumes one H^+ . The antiport of the dianionic oxalate against the monoanionic formate generates an electrical gradient (positive on the outside), and consumption of one H^+ ion by the decarboxylation generates a ΔpH (alkaline on the inside). The resulting proton potential is used to drive ADP phosphorylation by an H^+ -ATP synthase.

Decarboxylation of malate by lactic acid bacteria (malolactic fermentation: malate + $\text{H}^+ \rightarrow$ lactate + CO_2) uses a similar mechanism of energy conservation. In *Lactococcus lactis*, malate is taken up and converted by a cytoplasmic decarboxylase to lactate + CO_2 , consuming H^+ as a cosubstrate. Malate and lactate are transported by an electrogenic antiporter, generating an electrical potential (positive on the outside), and H^+ ion consumption in the cytoplasm during decarboxylation generates a ΔpH value (alkaline on the inside). The proton potential can be used for driving ADP synthesis by a membranous ATP synthase.

Anoxygenic Photosynthetic Prokaryotes

Anoxygenic photosynthetic bacteria use only one photosystem for converting light energy into an electrochemical proton

potential, which is then used for driving ADP phosphorylation. Anoxygenic photosynthetic bacteria are found in three different phylogenetic groups, which contain different photosynthetic systems: the purple bacteria, the green phototrophic bacteria with the subgroups of green sulfur bacteria (*Chlorobiaceae*) and *Chloroflexus*, and the Gram-positive *Heliobacteria*. The three groups show differences in the type of photosynthetic reaction center, photosynthetic electron transfer and the electron donors, pigments, and the pathway for CO_2 fixation. In anoxygenic photosynthesis, light is used to raise electrons to a more electronegative redox potential and to feed the electrons into a cyclic electron transport to generate a proton potential. The bacteria contain only one reaction center in contrast to oxygenic photosynthesis in cyanobacteria, green algae, or plants. The photosystems of anoxic photosynthesis transfer the electrons either to quinones or to ferredoxin (quinone-type- or FeS-type reaction centers). The archaeon *Halobacterium salinarum*, on the other hand, contains a proton pump that is directly driven by light to translocate protons over the membrane without involvement of photosynthetic electron transport. In contrast to the photosynthetic bacteria that use chlorophyll containing proteins for photosynthesis and energy conversion, *Halobacterium* contains bacteriorhodopsin with retinal as a chromophore for light absorption and conversion to an electrochemical proton potential.

Glossary

Biological efficiency The ability of an enzyme inhibitor to achieve significant inhibition at the physiological conditions of substrates and cofactors.

Catalytic site A cavity on the enzymatic surface that binds substrates and causes them to be converted to product by increasing the probability that they will achieve the transition state.

Inhibitor design Selection or synthesis of stable molecules intended to disrupt catalytic function of a specific enzyme.

Mechanism-based inhibitor A molecule resembling a substrate that is chemically activated by the action of

the enzyme to form a stable covalent link with the enzyme – also known as suicide substrates or suicide inhibitors.

Substrate analog A molecule with shape and charge features similar to a substrate of the enzyme that binds at the catalytic site and prevents substrate binding.

Transition-state analog A chemically stable molecule with shape and electrostatic features that mimic those of the transition state and that inhibit at the catalytic site by converting energy of catalysis to energy of binding.

Reversible Catalytic-Site Inhibitors

Reactant and Product Analogs

Molecules with shape and charge similar to the substrate or products may bind to the catalytic site similar to the normal reactants. When they are bound, the substrate cannot bind and the enzyme is prevented from catalyzing the reaction. The relative affinity of these competing molecules for the catalytic site and their abundance relative to the substrate will determine if they prevent substrate binding (Figures 1 and 2). Thus, if reactants and inhibitors bind with equal affinity, at equal concentrations, the enzyme catalytic site will be equally occupied with reactants and inhibitor resulting in 50% inhibition. This relationship is described in quantitative terms by the competition between an inhibitor (I) and a reactant (A) for a simple enzyme with one reactant by the equation $v = (k_{\text{cat}})(A)/(K_m + A(1 + I/K_i))$ where v is the enzymatic reaction rate, k_{cat} is the maximum catalytic rate of the enzyme, K_m is related to the binding affinity between enzyme and substrate, defined as the concentration of substrate to achieve 50% of k_{cat} in the absence of inhibitor, and K_i is the dissociation constant for the enzyme–inhibitor complex, defined by the equation $K_i = (E)(I)/(EI)$, and A and I are reactant and inhibitor concentrations, respectively. Diagrams of substrate and product inhibition illustrate the mutually exclusive or competitive inhibition relative to the catalytic site (Figure 2). Complete graphical and mathematical analyses of enzyme inhibition cases are available.

Bisubstrate Mimics

Many enzymatic reactions combine two different molecules at the catalytic site to transfer a chemical group between them. An example is the enzyme adenylate kinase that transfers the terminal phosphoryl group of adenosine triphosphate (ATP) to adenosine monophosphate (AMP) to generate two molecules of adenosine diphosphate (ADP; Figure 3). The catalytic

site must accommodate ATP and AMP at the same time in preparation for group transfer. The bisubstrate mimic for the adenylate kinase reaction is chemically similar to ATP combined with AMP to make a bisubstrate molecule called AP₅A (Figure 3). Such molecules compete for both substrate sites, since they prevent either substrate from binding by competition for the same sites. Bisubstrate mimics can bind tightly to the enzyme since connected molecules bind with affinity equal to the product of the affinity of the individual molecules. For example, if individual dissociation constants (K_i values) for ATP and AMP are both 10^{-4} M, the dissociation constant for the bisubstrate mimic would be expected to be related to the product of these constants or $10^{-4} \times 10^{-4}$ M = 10^{-8} M.

Transition-State Analogs

A special class of competitive inhibitors resembles the reactant molecule at the very point where it crosses the chemical energy equivalence point of bond breaking/bond making called the transition state. These inhibitor molecules must be chemically stable, but have close similarity to the unstable transition state. Based on the theory of transition-state stabilization for enzyme-catalyzed reactions, the perfectly designed transition-state analog is capable of binding to the enzyme by the factor: K_i for transition-state inhibitor = K_m /catalytic rate enhancement. Since enzymatic catalytic rate enhancements are typically 10^{10} – 10^{15} , perfectly designed transition-state inhibitors can bind 10^{10} – 10^{15} times better than substrate. These incredibly large affinities have been rarely achieved. It is impossible to match the nonequilibrium bond lengths and partial charges present at the precise moment of the transition state with chemically stable molecules. However, incorporation of even modest similarities between the actual transition state and transition-state analogs can achieve binding affinities 10^5 – 10^7 times that of reactants, and this improvement is adequate to achieve inhibition of the targeted enzymes in biological systems.

Figure 1 A schematic for the steps in enzyme-catalyzed reactions. In the first step, diffusion causes collision between the substrate and an open catalytic site. The weakly bound enzyme–substrate complex causes the protein to close to form the tightly bound enzyme–substrate complex. Hydrogen bonds (H–R), ionic bonds (+–), and hydrophobic interactions (><) in this closed complex at the transition state are shown. Following bond changes, the enzyme–product complex relaxes to release product and regenerate the original form of the enzyme to repeat the cycle.

Enzymatic transition states

This point of the chemical reaction is often the most energetic point in the reaction cycle, and therefore the rarest and the most difficult to detect. The exact shape and charge of the substrate molecule at the moment of the transition state is of great interest, since chemically stable molecules that resemble the substrate molecule at the transition state bind extremely tightly to the enzyme, as discussed above. This concept was proposed early in the history of biochemistry by Linus Pauling, and was formalized several decades later by Richard Wolfenden. An example of the substrate, enzyme-stabilized transition state and a transition analog for purine nucleosidase phosphorylase is shown (Figure 4). These inhibitors commonly bind to the catalytic sites of enzymes millions of times more tightly than the substrates. Many of the antibiotics isolated in nature have been found to be transition-state analogs. Recently, molecules designed to be transition-state analogs are being tested in medical applications such as anticancer agents. Transition-state inhibitors compete at the catalytic site and cause the enzyme to fold into its tightly binding mode and keep it closed for long times, preventing catalysis (see Figure 1).

Design of transition-state analogs

Both the shape and charge of reactant molecules change as they reach the transition state (see Figure 1). The structure of the transition state can be experimentally measured by using kinetic isotope effects, combined with computational chemistry to locate the enzymatic transition state. The electron distribution at the van der Waals surface of a molecule is called its

molecular electrostatic potential surface. This can be described for substrate and transition states for enzyme reactions provided the transition-state structure is known, and can also be established for proposed inhibitor molecules. Electrostatic matches to the transition state make powerful inhibitors by capturing some of the transition-state energy usually applied to catalysis (Figure 4).

Natural product transition-state analogs

Many antibiotics isolated from natural sources are transition-state inhibitors. One example is an antibiotic formed in the culture medium of *Streptomyces antibioticus* that is apparently made as an agent of microbial warfare between species of soil organisms. R-coformycin binds to the catalytic sites of adenine nucleoside and nucleotide deaminases millions of times tighter than the reactant molecules. The transition-state structure for deaminase enzymes has been solved and the similarity of transition-state analog and transition state is greater than that of either to the substrate (Figure 5).

Noncatalytic Site Inhibitors

Noncatalytic site inhibitors include all inhibitors binding at sites other than the catalytic site. These inhibitor molecules can cause several different types of enzymatic inhibition, both competitive and noncompetitive. This diversity arises as a result of the inhibitor binding distant to the catalytic site, which changes the enzyme conformation that prevents the enzyme from functioning properly, either in binding its substrate or in forming products.

Figure 2 Enzyme A is a normal Michaelis complex with substrate a–b at the catalytic site (yellow). The bond to be broken by the enzyme connects a and b. The substrate-like competitive inhibitor (pink, enzyme B) has a difference in the B part of the bound molecule and is not a substrate but competes directly for a–b at the catalytic site. Since this is a competition, large amounts of a–b will displace a–B. A noncompetitive inhibitor binds to influence catalysis but does not directly compete for the catalytic site. There are many variants of noncompetitive inhibition and binding at a remote site to change features of the catalytic site is one example (green in enzyme C). Competitive inhibitors can also be product-like as shown in enzyme D (pink).

Figure 3 The Michaelis complex for adenylate kinase ($\text{ATP} + \text{AMP} \rightarrow 2\text{ADP}$) is shown on the left with the arrows indicating electron flow for the phosphoryl group transfer. The inhibited complex with adenosyl-pentaphosphate-adenosine (A-P5-A) is on the right. The bisubstrate inhibitor competes for both ATP- and AMP-binding sites. Ionic charges are omitted for clarity and the ribosyl groups are all β -D-ribose in stereochemistry.

Prevent Catalytic Site Binding

An inhibitor may bind remote from the catalytic site to change the protein conformation and cause mutual exclusion between

reactant binding at the catalytic site and inhibitor binding at the remote site. For this interaction, kinetic analysis of the type shown above will be kinetically indistinguishable from competitive inhibition. The surfaces of proteins contain highly irregular

Figure 4 The reaction catalyzed by bovine purine nucleoside phosphorylase (PNP), transition-state structure, and a transition-state analog inhibitor (immucillin-H). Novel features of the transition state are protonation at N7 and the partial positive charge on the ribosyl group. Both are represented in the inhibitor, shown in blue. Immucillin-H binds approximately 1 million times more tightly to PNP than does the substrate inosine. Shown below are the electronic van der Waals surfaces of inosine (left), transition state (middle), and immucillin-H (right). Note the electrostatic similarity between transition state and Immucillin-H. Reproduced from Schramm VL (2002) Development of transition state analogues of purine nucleoside phosphorylase as anti-T-cell agents. *Biochimica et Biophysica Acta* 1587: 107–117.

and charged surfaces that interact with specific molecules. Current practice of testing libraries of diverse chemical compounds against a specific enzyme to find any type of interaction that can cause inhibition often discovers this class of inhibitor.

Prevent Subunit Formation

Most enzymes have multiple protein subunits that must interact to provide a functional catalytic unit. An example is the ribonucleotide diphosphate reductase required to form deoxynucleotides for the biological production of DNA. During cellular protein synthesis of these enzymes, the protein subunits are formed separately and must then combine to make the functional catalyst. In the cell, these subunits are thought to separate and recombine many times, providing an opportunity to insert an inhibitory molecule in the protein interface between subunits. Selection of such molecules from chemical libraries or designing them from known

protein–protein interfaces prevents formation of the active enzyme molecule in the cell. Inhibitors of this type have been designed for ribonucleotide diphosphate reductase and show promise in this new area of specific inhibitor design.

Prevent Conformational Change for Catalysis

A related inhibitor type is one binding remote from the catalytic site to prevent an enzymatic conformational change that is required for catalysis. Most enzymes require protein motion to close the catalytic site prior to the formation of the transition state. These loops or domain motions involve physical motion of segments of the proteins, often over relatively large distances. A consequence of the motion is to position amino acid residues in the catalytic site where they are required for catalysis. An inhibitor that binds outside the catalytic site and prevents this protein motion required for catalysis will provide complete loss of enzyme function without blocking access of

Figure 5 Reactant (adenosine), transition state, and transition-state analog inhibitor for adenosine deaminase. R-coformycin is a natural product transition-state analog inhibitor that binds 10 million times tighter to adenosine deaminase than does adenosine.

Figure 6 Covalent suicide inhibition of ornithine decarboxylase by DFMO. In the normal reaction, the enzymatic cofactor, pyridoxal phosphate, forms a Schiff base favoring decarboxylation of ornithine. With DMFO, the same steps occur but decarboxylation generates a reactive difluoro-conjugated imine. A nearby cysteine nucleophile reacts to form a stable, inactive enzyme.

reactants to the catalytic site. As knowledge of the protein surfaces becomes more complete, it will be increasingly possible to design molecules that participate in these novel inhibitory roles.

Mechanism-Based Inhibitors

Mechanism-based enzymatic inhibitors are designed to be stable molecules that resemble the substrate. They bind at the catalytic site of the target enzyme and are converted by the enzyme to a chemically reactive form that covalently reacts with the catalytic site of the enzyme. This covalent intermediate of enzyme inhibitor differs from normal catalytic intermediates by its chemical stability and long lifetime. Trapping the enzyme in a stable covalent complex blocks the catalytic site from normal interaction and provides long-term inhibition of the enzyme. Mechanism-based inhibitors are in broad use in biology, and our example of this chemical inhibitor logic is in the pathway of polyamines (Figure 6).

Polyamine Synthesis

The polycationic polyamines are essential counterions for DNA replication in dividing cells. The first step in polyamine synthesis is catalyzed by ornithine decarboxylase which uses a transient covalent intermediate to the enzymatic cofactor pyridoxal phosphate. Difluoromethylornithine (DFMO) is decarboxylated in similar fashion to ornithine, but the reaction creates a highly reactive intermediate that reacts with a nearby group on the enzyme to form a stable covalent intermediate, resulting in an inactive ornithine decarboxylase. It therefore stops polyamine biosynthesis. It has been used as an anticancer agent and an antibiotic against *Trypanosoma* species that cause sleeping sickness. Specificity is provided by the binding of DFMO only to the target enzyme and long biological action is provided by the stable covalent interaction with the enzyme. These are features of most mechanism-based enzyme inhibitors.

Care is needed that chemical reactivity causing enzymatic inactivation is revealed only to the target enzyme.

Other Mechanism-Based Inhibitors

Many of the common anti-metabolites are mechanism-based inhibitors. Thus, certain insecticides form covalent interactions with the catalytic site of enzymes involved in insect neurotransmission. Deprenyl is a drug used to treat Parkinson's disease and mental depression by increasing brain dopamine levels. It functions by suicide inhibition at the catalytic site of monoamine oxidase, the enzyme that degrades dopamine.

Conclusion

The intricate steps in enzymatic action can be disrupted in numerous ways, each causing inhibition of catalytic steps. Enzymes have evolved to function in the presence of the complex mixture of normal cellular components, but inhibitors can be designed to specifically target a single enzyme of the thousands that function in coordination in a normal cell.

Glossary

Catalytic rate constant (k_{cat}) Moles of substrate converted to product per second per mole of enzyme active site; it is also called active-site turnover number.

Kinetic mechanism The order in which substrates add and products are released in an enzyme-catalyzed reaction.

Maximal velocity (V_{max}) Maximum reaction rate (v observed at saturating substrate concentrations) for a given concentration of enzyme: $V_{\text{max}} = k_{\text{cat}}[E]_{\text{t}}$.

Michaelis constant (K_{m}) Kinetic constant equivalent to the concentration of the varied substrate that yields half-maximal velocity when all other substrates are saturating.

Rapid equilibrium Condition where the ligands and enzyme species present are at chemical equilibrium.

Steady state Condition where the rate of formation of an intermediate is equal to the rate of its utilization.

Unireactant Enzymes and the Michaelis–Menten Equation

By the mid- to late 1800s, most of the laws governing the effect of reactant concentrations on the rates of chemical reactions were known. However, enzyme-dependent reactions did not always follow these simple rate laws. In 1902, Victor Henri proposed the first useful equation for an enzyme-dependent reaction. Henri's equation took into account the known properties of enzymes, including that (1) an enzyme was highly specific for a particular substrate (or class of substrates), (2) the substrates often protected an enzyme from inactivation by heat, and (3) a plot of initial velocity versus substrate concentration was hyperbolic. (These properties all pointed to the participation of an enzyme–substrate complex.) Subsequent workers, including Michaelis and Menten (1913), Van Slyke and Cullen (1914), and Briggs and Haldane (1925), confirmed and/or extended Henri's equation, which is derived below.

The Rapid Equilibrium Assumption

The following assumptions and procedures led Henri and others to the relationship between substrate concentration and reaction rate, which is now known as the Michaelis–Menten equation:

1. The overall reaction occurs in two steps, as shown below:

This sequence recognizes that the enzyme is not consumed in the reaction, but rather is a recycling catalyst. The first step is the rapid equilibration of the free enzyme (E) and the free substrate (S) to form an ES complex. This is followed by the unidirectional, rate-limiting decomposition of ES to E + P. The rapid equilibrium between E, S, and ES is maintained throughout the course of the reaction. (This condition requires that $k_{-1} \gg k_2$.) The equilibrium is described by the dissociation constant, K_s , of the ES complex:

$$K_s = [E][S]/[ES] = k_{-1}/k_1 \quad [2]$$

Equation [2] allows the concentration of the ES complex to be expressed in terms of the concentration of free E, free S, and K_s :

$$[ES] = [S][E]/K_s \quad [3]$$

2. At any time, the total enzyme, $[E]_{\text{t}}$, is present either as free E or as the ES complex. Thus, the mass balance (conservation) equation is

$$[E]_{\text{t}} = [E] + [ES] \quad [4]$$

The total substrate is also distributed between the free and complexed species:

$$[S]_{\text{t}} = [S] + [ES] \quad [5]$$

However, for most enzyme-dependent reactions that are studied *in vitro*, the enzyme is present at a very low (catalytic) level (i.e., $[E]_{\text{t}} \ll [S]_{\text{t}}$), so that the maximum $[ES]$ that can form will be much smaller than the $[S]_{\text{t}}$ added. Consequently, it can be assumed that the free S concentration is essentially identical to the total added S (i.e., $[S] \approx [S]_{\text{t}}$). This assumption is not valid for many enzymes inside the cells, where $[E]_{\text{t}}$ may be in the same range as $[S]_{\text{t}}$.

3. The instantaneous or initial rate, $d[P]/dt$ or $-d[S]/dt$ (usually indicated as v for velocity), is proportional to the concentration of the ES complex:

$$v = k_2[ES] \quad [6]$$

4. It is assumed that the accumulating product has no effect on the reaction. That is, the P concentration remains close to zero throughout the course of the reaction, or P has no affinity for the enzyme.
5. The final velocity equation is obtained by dividing eqn [6] by eqn [4] and substituting for $[ES]$ from eqn [3]:

$$\frac{v}{[E]_{\text{t}}} = \frac{k_2[ES]}{[E] + [ES]} \quad \text{or} \quad v = \frac{k_2[E]_{\text{t}} \frac{[S][E]}{K_s}}{[E] + \frac{[S][E]}{K_s}} \quad [7]$$

$k_2[E]_t$ is defined as $V_{\max}$ because when all the enzyme is in the ES form, the observed velocity will be maximal. This substitution and canceling $[E]$ in eqn [7] yields the final Michaelis–Menten equation:

$$v = \frac{V_{\max} \frac{[S]}{K_s}}{1 + \frac{[S]}{K_s}} = \frac{V_{\max}[S]}{K_s + [S]} \quad [8]$$

The Steady-State Assumption

By the 1920s, researchers realized that the rapid equilibrium assumption was too restrictive and would not be valid for enzymes where the ES complex proceeds on to E + P much faster than it dissociates back to E + S. In such cases, E, S, and ES would not attain equilibrium. In 1925, Briggs and Haldane offered a more general method for deriving velocity equations that did not require a rapid equilibrium assumption. Their steady-state approach recognized that under most assay conditions, $[E]$ and $[ES]$ would attain certain levels very quickly after mixing E and S, but that the concentrations of these enzyme species would change very little thereafter. In other words, for the duration of the assay, the rate at which ES is formed (from E + S) remains identical to the rate at which it decomposes (back to E + S, plus forward to E + P). Similarly, the rate at which E is produced from ES equals the rate at which E is used to form ES. Equation [1] is still applicable, but now rate constants for individual steps must be taken into account. Applying the steady-state assumption we can write

$$d[ES]/dt = 0 \text{ or } k_1[E][S] = (k_{-1} + k_2)[ES] \quad [9]$$

and

$$d[E]/dt = 0 \text{ or } (k_{-1} + k_2)[ES] = k_1[E][S] \quad [10]$$

Solving either equation for $[ES]$ yields

$$[ES] = k_1[E][S]/(k_{-1} + k_2) \text{ or } [ES] = [S][E]/K_m \quad [11]$$

where in the latter expression, the three rate constants are combined into a single kinetic constant, K_m , as shown below:

$$K_m = (k_{-1} + k_2)/k_1 \quad [12]$$

The initial velocity (v) at any $[S]$ still equals $k_2[ES]$. So, proceeding as described earlier, but substituting for $[ES]$ from eqn [11], we obtain

$$v = \frac{V_{\max}[S]}{K_m + [S]} \quad [13]$$

Thus, the velocity equation is the same as that derived for rapid equilibrium conditions, except that the constant in the denominator (now called a Michaelis constant) is more complex than a simple dissociation constant. The Briggs–Haldane approach is more general than the rapid-equilibrium approach because it makes no assumptions about the relative magnitudes of the various rate constants. If $k_2 \ll k_{-1}$, K_m reduces to k_{-1}/k_1 , which is equivalent to the simpler K_s .

Equation [13] is valid throughout the experimental $[S]$ range provided that the rate of P formation is measured before $[S]$ changes appreciably. (In practice, substrate use should be restricted to less than 5% (or at most 10%) of $[S]_t$.) When

$[S] \ll K_m$, eqn [13] reduces to $v = V_{\max}[S]/K_m = k[S]$, that is, the reaction is first order with respect to $[S]$ with a rate constant equivalent to $V_{\max}/K_m$. When $[S] \gg K_m$, v is essentially constant at $V_{\max}$ and independent of $[S]$. (The reaction is zero order with respect to $[S]$.)

A More Realistic Unireactant Reaction Sequence

Equation [1] contains the minimum number of steps that must be considered in the description of a uni–uni (one substrate, one product) reaction. A more realistic scheme takes into account the conversion of enzyme-bound S to enzyme-bound P (before P is released) and the reversibility of each step:

A steady-state treatment of the above reaction sequence once again yields the familiar Michaelis–Menten equation when $[P] = 0$, except that now

$$K_m = \frac{k_{-1}k_3 + k_{-1}k_{-2} + k_2k_3}{k_1(k_2 + k_{-2} + k_3)} \quad [15]$$

and

$$V_{\max} = \frac{k_2k_3[E]_t}{k_2 + k_{-2} + k_3} \quad [16]$$

So, in the absence of other information, the rate constant compositions of the two kinetic constants, K_m and $V_{\max}$, are not usually known. But regardless of its makeup, K_m is a valuable characteristic because it is equivalent to the substrate concentration that yields half-maximal velocity. $V_{\max}$ is not a true constant because it depends on the enzyme concentration. However, $V_{\max}/[E]_t$, expressed as moles of S converted to P per second per mole of enzyme active site (which reduces to per second, or s^{-1}) is the catalytic rate constant (or turnover number) of the enzyme, k_{cat} . The ratio k_{cat}/K_m has been used to compare the action of an enzyme on a series of related substrates. The higher the value of this specificity constant, the better the substrate. If an enzyme is evolutionarily perfected so that the catalytic and product release rate constants are very much larger than any of the reverse first-order rate constants, the ratio k_{cat}/K_m reduces to k_1 , the second-order rate constant for the interaction of E and S to form ES. In aqueous solution, this constant has a maximum, diffusion-limited value of $\sim 10^9 \text{ M}^{-1} \text{ s}^{-1}$. Many enzymes have k_{cat}/K_m values that approach this maximum.

Reversible Reactions

In the presence of both the substrate and product, the net steady-state velocity is given by the difference between the forward and reverse rates of any step, for example,

$$v = k_2[ES] - k_{-2}[EP] \quad [17]$$

or

$$\frac{v}{[E]_t} = \frac{k_2[ES] - k_{-2}[EP]}{[E] + [ES] + [EP]} \quad [18]$$

After substituting for $[ES]$ and $[EP]$ and grouping rate constants into kinetic constants, the equation is

$$v = \frac{V_{\max, f} \frac{[S]}{K_{mS}} - V_{\max, r} \frac{[P]}{K_{mP}}}{1 + \frac{[S]}{K_{mS}} + \frac{[P]}{K_{mP}}} \quad [19]$$

where $V_{\max, f}$ and $V_{\max, r}$ are the forward and reverse maximal velocities, respectively; K_{mS} and K_{mP} are the Michaelis constants of S and P, respectively. Equation [19] can also be written as

$$v = \frac{V_{\max, f} [S]}{K_{mS} \left(1 + \frac{[P]}{K_{mP}}\right) + [S]} - \frac{V_{\max, r} [P]}{K_{mP} \left(1 + \frac{[S]}{K_{mS}}\right) + [P]} \quad [20]$$

which shows that in this unireactant process, P acts as a competitive inhibitor of the forward reaction and S acts as a competitive inhibitor of the reverse reaction. (In reactions catalyzed by multireactant enzymes, individual products might be competitive, uncompetitive, or noncompetitive with respect to different substrates.)

The Velocity Curve and Its Linear Forms

Figure 1 shows the typical hyperbolic dependence of the velocity of an enzyme-catalyzed reaction on the substrate concentration. The kinetic constants, K_m and $V_{\max}$, can be obtained by fitting the v versus $[S]$ data directly to the Michaelis–Menten equation using an appropriate computer application. Alternatively, K_m and $V_{\max}$

Figure 1 Theoretical plot of initial velocity vs. substrate concentration in the absence of the product for an enzyme with a K_m of 0.5 mM and a $V_{\max}$ of 100 $\mu\text{mol min}^{-1} \text{mg}^{-1}$ protein. The $[S]$ at which v is 50% of $V_{\max}$ (i.e., $[S]_{0.5}$) is equivalent to K_m . The curvature of the plot is the same for all enzymes obeying Henri–Michaelis–Menten kinetics, regardless of the absolute values of the kinetic constants. For example, the ratio of substrate concentration that yields 90% of $V_{\max}$ ($[S]_{0.9}$) to that yielding 10% of $V_{\max}$ ($[S]_{0.1}$) is always 81. Similarly, the $[S]_{0.75}/[S]_{0.5}$ ratio is always 3. Note that $V_{\max}$ is difficult to determine visually. But a computer-assisted fit to $v = V_{\max} [S] / (K_m + [S])$ will return both $V_{\max}$ and K_m . (Inset) Double-reciprocal plot of the data. A wide range of substrate concentrations is needed to construct both the primary plot and the double-reciprocal plot because $[S]$ values that are evenly spaced on one plot do not space evenly on the other.

can be obtained by plotting the data in a linear form such as $1/v$ versus $1/[S]$ (usually called the Lineweaver–Burk or double-reciprocal plot), $v/[S]$ versus v (usually called the Scatchard plot), v versus $v/[S]$, or $[S]/v$ versus $[S]$. The most popular of these is the double-reciprocal plot, which is based on the linear transformation of the Michaelis–Menten equation:

$$\frac{1}{v} = \frac{K_m}{V_{\max}} \frac{1}{[S]} + \frac{1}{V_{\max}} \quad [21]$$

A major advantage of a linear plot is that data obtained at several different fixed concentrations of a second ligand (e.g., a co-substrate, product, inhibitor, or activator) can be displayed simultaneously and the resulting slope and intercept characteristics used to diagnose the kinetic mechanism or the mode of inhibition or activation.

Multireactant Enzymes

Common Mechanisms

Most enzymes catalyze reactions between two or more substrates to yield two or more products. The substrates bind to the enzyme either in a random manner or in a compulsory order. Similarly, product release is random in some cases, and ordered in the others. Mechanisms in which catalysis occurs only after two (or more) substrates are brought together on the enzyme are called sequential. Some enzymes catalyze the formation and release of a product before all the substrates have bound. For example, an enzyme might capture a substrate, A, and retain part of that molecule (sometimes as a covalent adduct with the enzyme) releasing the rest of the molecule as product P. Only then does substrate B bind and combine with the part of A that was left on the enzyme to form product Q, which then leaves. This type of substituted enzyme or ping-pong mechanism is common for transaminases; the amino group of substrate A is left temporarily on the enzyme. A reaction catalyzed by a terreactant (three-substrate) enzyme might proceed by a combination of sequential and ping-pong steps. The order of addition of substrates and release of products is called the kinetic mechanism. Four bireactant examples are shown in Figure 2.

Velocity Equations for Some Bireactant Mechanisms

In some cases, different kinetic mechanisms are described by different velocity equations. (see standard enzyme kinetics texts for the procedures used to derive these equations). Consequently, it is sometimes possible to distinguish between mechanisms from the characteristics of the double-reciprocal plots. For example, the velocity equation for an ordered bireactant mechanism under steady-state conditions in the absence of products is

$$v = \frac{V_{\max} [A][B]}{K_{ia} K_{mB} + K_{mB} [A] + K_{mA} [B] + [A][B]} \quad [22]$$

where K_{mA} and K_{mB} are the Michaelis constants of the two substrates and K_{ia} is the simple dissociation constant of the EA complex. (Velocity equations for multireactant mechanisms often contain both types of constants.) When $[A]$ is varied at different fixed concentrations of B, the velocity

Figure 2 Four common kinetic mechanisms for bireactant enzymes are shown in the Cleland shorthand notation. Substrates are indicated above a horizontal line as A, B, C, etc., in the order in which they add to the enzyme. Products are indicated as P, Q, R, etc., in the order in which they dissociate from the enzyme. Arrows are shown pointing in a single direction, but all the reactions are reversible. Rate constants for each reversible reaction are shown alongside arrows. For computer-based derivations of the velocity equation, it is usually more convenient to indicate all rate constants with positive subscripts (odd numbers for the forward steps; even numbers for the reverse direction). The various enzyme species present in the mechanism are placed below the horizontal line (in sequence of their formation). Species that are interconverted by a unimolecular step are usually grouped together within parentheses. (a) Random mechanism, (b) ordered mechanism, and (c) Theorell–Chance mechanism. The last is a limiting case of an ordered mechanism in which the EAB + EPQ central complex does not account for a significant fraction of the total enzyme in the steady state. (d) Ping-pong mechanism where stable enzyme forms F may be a covalent adduct of E with the part of substrate A left behind.

dependence can be written in the form of the Michaelis–Menten equation:

$$v = \frac{V_{\max}[A]}{K_{mA}\left(1 + \frac{K_{ia}K_{mB}}{K_{mA}[B]}\right) + [A]\left(1 + \frac{K_{mB}}{[B]}\right)} \quad [23]$$

or, in double reciprocal form:

$$\frac{1}{v} = \frac{K_{mA}}{V_{\max}} \left(1 + \frac{K_{ia}K_{mB}}{K_{mA}[B]}\right) \frac{1}{[A]} + \frac{1}{V_{\max}} \left(1 + \frac{K_{mB}}{[B]}\right) \quad [24]$$

When [B] is varied at different fixed concentrations of A, the equations are

$$v = \frac{V_{\max}[B]}{K_{mB}\left(1 + \frac{K_{ia}}{[A]}\right) + [B]\left(1 + \frac{K_{mB}}{[A]}\right)} \quad [25]$$

and

$$\frac{1}{v} = \frac{K_{mB}}{V_{\max}} \left(1 + \frac{K_{ia}}{[A]}\right) \frac{1}{[B]} + \frac{1}{V_{\max}} \left(1 + \frac{K_{mB}}{[A]}\right) \quad [26]$$

At a fixed concentration of one substrate, for example, A, the velocity dependence on the concentration of substrate B can also be described by a simplified form of eqn [25]:

$$v = \frac{V_{\max, \text{app}}[B]}{K_{mB, \text{app}} + [B]} \quad [27]$$

where the apparent constants are related to the true or limiting constants:

$$V_{\max, \text{app}} = \frac{V_{\max}}{\left(1 + \frac{K_{mB}}{[A]}\right)} \quad \text{and} \quad K_{mB, \text{app}} = \frac{\left(1 + \frac{K_{ia}}{[A]}\right)}{\left(1 + \frac{K_{mB}}{[A]}\right)} \quad [28]$$

In other words, the experimentally determined K_m and $V_{\max}$ depend on the concentration of the co-substrate and will not equal the limiting values unless that concentration is infinitely high (saturating). In practice, the limiting kinetic constants are obtained from appropriate replots of the slopes and $1/v$ -axis intercepts of the double-reciprocal plots. (The former is a replot of $K_{m, \text{app}}/V_{\max, \text{app}}$; the latter is a replot of $1/V_{\max, \text{app}}$.) For example, the replots for the family of $1/v$ versus $1/[B]$ plots at different fixed [A] are described by the following linear equations:

$$\text{int} = \frac{K_{mB}}{V_{\max}} \frac{1}{[A]} + \frac{1}{V_{\max}} \quad [29]$$

$$\text{slope} = \frac{K_{mB}K_{ia}}{V_{\max}} \frac{1}{[A]} + \frac{K_{mB}}{V_{\max}} \quad [30]$$

$V_{\max}$, K_{mB} , and K_{ia} can be determined from the intercepts of the replots.

The equation for the substituted enzyme (ping-pong) bireactant mechanism in the absence of products is

$$v = \frac{V_{\max}[A][B]}{K_{mB}[A] + K_{mA}[B] + [A][B]} \quad [31]$$

When [A] is varied at different [B], the Michaelis–Menten and double reciprocal equations are

$$v = \frac{V_{\max}[A]}{K_{mA} + \left(1 + \frac{K_{mB}}{[B]}\right)} \quad [32]$$

and

$$\frac{1}{v} = \frac{K_{mA}}{V_{\max}} \frac{1}{[A]} + \frac{1}{V_{\max}} \left(1 + \frac{K_{mB}}{[B]}\right) \quad [33]$$

The equations for varied [B] at different [A] are symmetrical to those shown for varied [A]. **Figure 3** shows the families of $1/v$ versus $1/[A]$ plots for an ordered and a ping-pong mechanism. In both mechanisms different fixed [B] values affect the vertical-axis intercepts. In the ordered mechanism, changing [B] also affects the slopes of the $1/v$ versus $1/[A]$ plots. However in the ping-pong mechanism, changing the fixed [B] has no effect on the slopes. (Note that eqns [24] and [33] predict these effects.) The absence of a slope effect is often sufficient to identify the ping-pong mechanism. But the presence of both the slope and intercept effects (as shown in **Figure 3(a)**) is not

Figure 3 Double-reciprocal plots of $1/v$ vs. $1/[A]$ at different fixed concentrations of B. A is called the varied substrate; B is called the changing fixed substrate. (a) A sequential mechanism. The plots could be for a steady-state ordered, Theorell–Chance, or a rapid-equilibrium random mechanism. (b) Ping-pong mechanism. For the above mechanisms, the plots of $1/v$ vs. $1/[B]$ at different fixed $[A]$ have the same appearance as for varied $1/[A]$. The limiting kinetic constants, $K_{m,A}$, $K_{m,B}$, $K_{i,A}$, V_{max} , etc., are obtained by replotting the slopes and/or $1/v$ -axis intercepts of the double-reciprocal plots against the reciprocal of the changing fixed substrate concentration.

sufficient to diagnose the mechanism as ordered because in the absence of products, a steady-state ordered, a Theorell–Chance, and a rapid-equilibrium random mechanism all have the same velocity equation. Consequently, the double-reciprocal plot patterns of the three different mechanisms are the same. Additional measurements are needed to distinguish between these mechanisms. Product inhibition studies can be informative. For example, in a steady-state ordered mechanism, one of the products (P, the first to dissociate from the enzyme) is noncompetitive with respect to both substrates, but in a Theorell–Chance and random mechanism, each product is competitive with at least one substrate. Dead-end inhibition studies may also be useful. For example, a nonreactive analog that is competitive with B will be uncompetitive with A in the ordered and Theorell–Chance mechanisms, but noncompetitive with A in the random mechanism. (This assumes that the inhibitor forms an EAI complex in the Theorell–Chance mechanism and mimics substrate B completely in the random mechanism by binding to both E and EA.)

Cleland's Slope and Intercept Rules

WW Cleland has presented a series of rules for predicting the effect of changing the fixed concentration of a co-substrate or product on the slopes and vertical-axis intercepts of $1/v$ versus $1/[\text{varied substrate}]$ plots. The slope and intercept effects are predicted separately and then combined to deduce the appearance of the double-reciprocal plot family. Conversely, the slope and intercept patterns can help diagnose the kinetic mechanism. The rules are as follows.

Intercept effect

A changing fixed substrate or product will cause an intercept effect if it and the varied substrate combine with different enzyme forms. However, there are exceptions: an intercept effect will not be seen for a changing fixed ligand that adds to the enzyme before the varied substrate under rapid-equilibrium conditions, or in a Theorell–Chance hit-and-run sequence between a substrate and the immediately released product (B and P in Figure 2(c)).

Slope effect

A changing fixed substrate or product will cause a slope effect if it and the varied substrate combine with the same enzyme form, or with different forms that are reversibly connected in the upstream or downstream direction. Two enzyme forms will not be reversibly connected if either (1) a product-release step occurs between them and that product is at zero concentration in the assay solution, or (2) a substrate-addition step occurs between the two enzyme forms and that substrate is present at a saturating concentration. Both the upstream and downstream directions must be blocked to eliminate reversibility.

A product will have no effect on slopes or intercepts if the steady-state level of the enzyme form with which it combines is zero because of saturation with a competitive substrate. Similar rules predict the slope and intercept effects produced by dead-end inhibitors.

Glossary

Enzyme-catalyzed reaction Although usually stereospecific, many of them are also stereoselective. The stereochemical property of an enzymatic reaction is useful in elucidating its reaction mechanism.

Stereoselectivity The ability of an enzyme to choose from two or more possible stereoisomers as a preferred substrate, to choose from two enantiotopic groups or from two

diastereotopic groups, or to produce one stereoisomer as a preferred product when more than one stereoisomeric products are possible.

Stereospecificity The ability of an enzyme to convert a particular stereoisomeric substrate to a specific stereoisomeric product. For a substitution reaction, the stereochemical course of a stereospecific reaction can be retention or inversion.

Explanation of Stereochemical Terms

Figure 1 uses chemical structures to illustrate key stereochemical terms. Stereoisomers (or stereo-isomers) are molecules that have the same molecular formula and the same order of attachment of atoms, but they differ in the way their atoms are oriented in space. Any molecule that cannot be superimposed on its mirror image is said to be chiral. Though chirality can result from a number of molecular properties, it is usually due to the presence of one or more carbon or phosphorus atoms, called chiral centers, which are surrounded by four unique substituents. Chiral molecules are classified as either enantiomers (stereoisomers that are mirror images of each other) or diastereomers (stereoisomers that are not mirror images of each other).

Configuration specifies how substituents are oriented around a chiral center and is determined by the *R*–*S* notation system, where *R* and *S* refer to the Latin terms *rectus* (right) and *sinister* (left). To assign *R*/*S* configuration, a priority rating is given to each substituent at a chiral center using the following rules: priority is first assigned on the basis of atomic number with highest priority given to the atom with the highest atomic number. When identical atoms are directly attached to the chiral center, the next atoms on the substituent are compared, until a difference is noted. Once priority has been established, the molecule is oriented so that the lowest priority substituent is pointing away from the viewer. The direction of rotation observed when moving from the highest to lowest priority will now be either clockwise or counterclockwise and the configuration is designated *R* or *S*, respectively.

An atom that is attached to two unique substituents and two identical substituents is said to be prochiral. The two identical groups at a prochiral center can be designated as pro-*R* and pro-*S* following a prochirality rule. As shown in Figure 1(c), the pro-*R* hydrogen (H_R) is the one that leads to *R* configuration if it is given a higher priority than the other hydrogen atom. When a chiral center or prochiral center is phosphorus instead of carbon, a subscript *p* is added (i.e., R_p , S_p , pro- R_p , and pro- S_p).

Stereoselectivity, Stereospecificity, and Stereochemical Course of Enzymatic Reactions

If exposed to a racemic mixture of substrates, most enzymes utilize one enantiomer or diastereomer preferentially. In reactions where chemistry is occurring at a prochiral center, an enzyme is also likely to act on just one of the two available enantiotopic or diastereotopic groups. The enzyme is said to be stereoselective in both cases.

Enzymatic reactions are usually stereospecific, which means that they convert one stereoisomer of substrate to one stereoisomer of product. For substitution reactions, stereochemical course refers to the change (or lack thereof) in configuration at the reaction center in a stereospecific reaction. While retention means the new group occupies the same position as the displaced group, inversion means it occupies the opposite position. If the reaction is nonstereospecific, it leads to racemization, with both isomers being formed at a ratio close to 1:1. Note that an *R*-substrate does not necessarily give an *S*-product in an inversion reaction, since the priority of the substituents at the reaction center can be altered on going from substrate to product. Also note that there is a steric course (inversion or retention) even when the displacement occurs at a prochiral center or a pro-prochiral center (a methyl group or phosphoryl group). The three hydrogen atoms of a methyl group and the three oxygen atoms of a phosphoryl group are homotopic and cannot be differentiated from one another by an enzyme. In these cases, there is no issue of stereoselectivity, only steric cause. Experimentally, pro-prochiral centers can be made chiral via isotope substitution, which in turn allows elucidation of the steric course of the reaction as illustrated in Figure 2.

In addition to the use of oxygen isotopes, an oxygen atom at a prochiral or pro-prochiral center can also be replaced by a sulfur atom. These phosphorothioate analogs have found broad applications in the study of diverse biological systems. The stereochemical course of phosphatases, which convert a phosphomonoester to inorganic phosphate, have been deciphered in this manner, as illustrated in Figure 2(d).

Figure 1 Demonstration of stereochemical terms using structures. (a) Though molecules 1, 2, and 3 have the same molecular formula, only 2 and 3 are stereoisomers. Molecule 1 has a different pattern of bonding (i.e., a different linkage of atoms) and is therefore a structural isomer of molecules 2 and 3. (b) Alanine stereoisomers are enantiomers since they are mirror images of each other. Note that the different configuration of substituents about the central carbon makes it impossible to superimpose the two isomers. (c) Glycine is achiral and therefore does not have stereoisomers. However, the central carbon is a prochiral center since it can be converted to a chiral center by replacing one of the two hydrogens with a different group. The two hydrogens are said to be enantiotopic since the separate replacement of each hydrogen results in a pair of enantiomers. (d) The two stereoisomers of threonine shown are diastereomers, that is, stereo-isomers that are not complete mirror images of each other. Note that this pair of molecules results by altering the configuration at C_α while leaving the configuration at the C_β unmodified. (e) Serine contains a chiral center at C_α and a prochiral center at C_β . Unlike glycine, the two hydrogen atoms at the prochiral center of serine are diastereotopic groups since the separate replacement of each hydrogen results in a pair of diastereomers.

Key steps in conducting stereochemical experiments are the synthesis of isomers of chiral substrates and/or substrate analogs and the analysis of a compound's stereochemical configuration before and after being processed by an enzyme. Since different substrate analogs are required for each enzyme studied, and since isotopes are frequently used, these studies are particularly challenging.

Pioneering Study: Alcohol Dehydrogenase

Yeast alcohol dehydrogenase (ADH) catalyzes the reversible transfer of a hydrogen atom between a molecule of ethanol

and a molecule of the coenzyme nicotinamide-adenine dinucleotide (NAD^+). By the use of deuterated ethanol or coenzyme, ADH was shown to abstract the pro-*R* hydrogen of ethanol and adding it to the *re* face of NAD^+ , as illustrated in Figure 3.

Analysis of Steric Course to Probe an Enzymatic Reaction Pathway

In nonenzymatic reactions, a bimolecular S_N2 reaction leads to inversion of configuration of the chiral carbon, while a unimolecular S_N1 reaction generates a planar carbonium ion that

Figure 4 Proposed sequential and parallel mechanisms for the formation of IcP and IP catalyzed by mPI-PLC. In the sequential mechanism, intramolecular attack by the axial ring hydroxyl forms the cyclic intermediate (IcP), which is then broken down by hydrolysis (H_2^{18}O) to give R_P -[^{16}O , ^{17}O , ^{18}O] IP. In the parallel mechanism, intramolecular attack by the axial ring hydroxyl and direct water (H_2^{18}O) attack gives S_P -[^{16}O , ^{17}O , ^{18}O] IP, respectively.

Figure 5 Metal-nucleotide interactions showing that substitution of Mg^{2+} by Cd^{2+} leads to a change in the stereoselectivity of AK from R_P -ATP β S to S_P -ATP β S.

interactions. A reversal (or a dramatic change) of stereoselectivity in the presence of an unnatural metal ion or upon mutating an active site residue provides strong evidence that the metal ion or mutated residue interacts with that particular phosphate moiety. Studies of adenylate kinase (AK) described below further illustrate this point.

AK catalyzes the reversible phosphoryl transfer reactions: $\text{Mg}^{2+} \cdot \text{ATP} + \text{AMP} \rightleftharpoons \text{Mg}^{2+} \cdot \text{ADP} + \text{ADP}$. Of the R_P and S_P isomers of ATP β S shown in Figure 5, AK prefers the S_P isomer by a factor of 9 in the presence of Mg^{2+} . However, this stereoselectivity is reversed (R_P isomer is preferred by a factor of 10) when Mg^{2+} is substituted by Cd^{2+} . Since Cd^{2+} preferentially coordinates sulfur over oxygen, which is opposite to the ligand preference of Mg^{2+} , the switch of stereospecificity upon Cd^{2+} substitution is strong evidence for direct coordination of the metal ion by the pro-S oxygen of the β -phosphate of ATP. Additional mechanistic information for AK was derived using active site mutants. Wild-type AK catalyzes the stereoselective conversion of adenosine monophosphates (AMPs) to S_P -ADP α S. Such stereoselectivity could be achieved by restricting orientation of the P-S and P-O bonds at the active site as shown in Figure 6. Experimental results demonstrated that

Figure 6 Enhancement and reversal of adenylate kinase stereoselectivity by site-directed mutagenesis (Ad, adenosine). In the reaction catalyzed by WT protein, phosphate is preferentially attached to the pro- R oxygen of AMPs. The R97M and R44M mutations enhance and reverse this stereoselectivity, respectively. This provides strong evidence that R97 and R44 interact with the phosphate moiety of AMP at the transition state. (a) and (b) represent two conformers of AMPs when bound to the active site of the enzyme.

the stereoselectivity of this reaction is further enhanced by the R97M mutant, but is completely reversed in the reaction catalyzed by the R44M mutant. These results indicate that the conformational equilibrium of the AMP substrate in the active site is perturbed in both mutants, suggesting that the Arg97 and Arg44 residues interact with the phosphate moiety of AMPs.

Glossary

Long-range linkage A conformational mechanism whereby phosphorylation and Ca^{2+} -binding domains are functionally coupled through a large intramolecular distance, within the adenosine triphosphatase (ATPase) molecule.

Partial reactions The sequential steps of the sarcoendoplasmic reticulum Ca^{2+} ATPase (SERCA) catalytic and transport cycles, including Ca^{2+} and ATP binding to the enzyme, formation of phosphoenzyme intermediate,

translocation of bound Ca^{2+} against a concentration gradient, and hydrolytic cleavage of phosphate.

Sarcoendoplasmic reticulum Ca^{2+} ATPase (SERCA) The membrane-bound ATPase involved in Ca^{2+} transport and refilling of intracellular Ca^{2+} stores.

Trigger points The phosphorylation domain and Ca^{2+} -binding site II where phosphorylation and occupancy by a Ca^{2+} trigger the long-range linkage for interconversion of phosphorylation and Ca^{2+} -binding potentials.

ATP Use for Ca^{2+} Transport

The sarcoendoplasmic reticulum calcium adenosine triphosphatase (ATPase) (SERCA) is the Ca^{2+} pump of intracellular membranes. The pump plays a prominent role in numerous cytosolic-signaling mechanisms that require the sequestration of intracellular Ca^{2+} . The SERCA pump was first noted in a microsomal fraction of rabbit skeletal muscle homogenates, which was found to prevent activation of glycerinated muscle fibers or isolated contractile models upon the addition of adenosine triphosphate (ATP). The microsomes were then identified with vesicular fragments of sarcoplasmic reticulum (SR), and the relaxing effect was attributed to the sequestration of Ca^{2+} from the medium through active transport by a membrane-bound ATPase. Complementary DNA (cDNA) cloning identified three gene products (SERCA1, SERCA2, and SERCA3) with two to three splice variants for each primary transcript. The related isoforms display specific tissue distribution, functional roles, and regulatory mechanisms.

The SR vesicles obtained from skeletal muscle contain a high quantity of Ca^{2+} ATPase (SERCA1A isoform), which accounts for approximately 50% of the total protein and which is densely spaced within the plane of the membrane (Figure 1). These vesicles provide a very useful experimental system inasmuch as they allow parallel measurements of ATPase activity and Ca^{2+} transport, as well as control of the ionic environment in compartments delimited by the native membrane. For this reason, they have been used extensively in biochemical and structural studies to clarify the mechanism of ATP use for Ca^{2+} transport.

Steady-State Behavior

Active transport of Ca^{2+} into the lumen of SR vesicles occurs with a stoichiometric ratio of two Ca^{2+} per hydrolyzed ATP under optimal steady-state conditions. Acetyl phosphate or *p*-nitrophenyl phosphate can be used as a substrate by the enzyme instead of ATP, although with lesser kinetic competence. The maximal levels of ATP-dependent Ca^{2+} uptake by

the vesicles is increased by Ca^{2+} binding to a native acidic protein, calsequestrin, in the lumen of the vesicles. It can also be increased by complexation with anions such as oxalate or phosphate in the lumen of the vesicles.

Independent of the substrate, the ATPase has a strict requirement for Ca^{2+} activation. In fact the enzyme is activated by a medium containing free Ca^{2+} within the micromolar range and is inhibited by lumenal-free Ca^{2+} in the millimolar range. This indicates that ATP is used to change the affinity and orientation of the Ca^{2+} -binding sites, resulting in a three-orders-of-magnitude Ca^{2+} gradient across the membrane. Furthermore, in reconstituted ATPase preparations that are deprived of pathways for passive leakage, it was shown that Ca^{2+} transport is accompanied by H^{+} countertransport at a 1:1 ratio and that the pump is electrogenic.

Considering these functional features, the free energy required for active transport of Ca^{2+} into the vesicles can be defined, at first approximation, as:

$$\Delta G = RT \ln ([\text{Ca}_{\text{in}}^{2+}]/[\text{Ca}_{\text{out}}^{2+}]) + zF\Delta V$$

where $[\text{Ca}_{\text{in}}^{2+}]$ and $[\text{Ca}_{\text{out}}^{2+}]$ refer to the Ca^{2+} concentration in the lumen of the vesicles and in the outer medium, z is the electrical charge of the transported species, R and F are the gas and Faraday constants, respectively, and ΔV is the transmembrane electrical gradient. The free-energy requirement, estimated in this manner, provides a satisfactory match of the experimentally observed gradients with the chemical potential of ATP.

The Partial Reactions of the Catalytic and Transport Cycles

The Ca^{2+} ATPase catalytic cycle includes a phosphorylated intermediate formed by covalent transfer of the ATP terminal phosphate to an aspartyl residue (Asp351) at the catalytic site. Phosphoryl transfer requires activation by the same Ca^{2+} concentration as ATP hydrolysis, indicating that enzyme activation by Ca^{2+} must occur early in the catalytic cycle. In fact, cooperative binding of two Ca^{2+} per ATPase in the absence of ATP, with

Figure 1 Structural characterization of SR vesicles. (a) Negatively stained SR vesicles, obtained from rabbit skeletal muscle, are visualized by electron microscopy. The densely spaced granules on the surface of the membrane correspond to Ca^{2+} ATPase molecules. (b) Electrophoretic analysis demonstrating that the Ca^{2+} ATPase separates as a prominent band that accounts for the major portion of the membrane protein. Adapted from Scales D and Inesi G (1976) Assembly of ATPase protein in sarcoplasmic reticulum membranes. *Biophysical Journal* 16: 735–751.

an apparent K_d in the micromolar Ca^{2+} range, was demonstrated by direct equilibrium measurements (Figure 2(a)).

The sequence of partial reactions making up the catalytic cycle was unveiled by transient-state experiments showing that addition of ATP to SR vesicles preincubated with micromolar Ca^{2+} is followed by the rapid formation of phosphorylated intermediate and vectorial displacement of two bound Ca^{2+} per ATPase. These initial events are then followed by hydrolytic cleavage of inorganic phosphate (Pi) after a time lag for protein conformational changes involved in the energy transduction mechanism (Figure 2(b)). On the other hand, the ATPase cycle is highly reversible, as demonstrated by ATP synthesis coupled to the Ca^{2+} efflux from loaded vesicles. The partial reactions of the reverse cycle were further clarified by the finding that, in the absence of bound Ca^{2+} , the enzyme can be phosphorylated with Pi to yield adenosine diphosphate (ADP)-insensitive phosphoenzyme (E-P). This phosphoenzyme can then be made ADP-sensitive by the addition of millimolar Ca^{2+} , whereupon it reacts with ADP to form ATP.

These functional findings have been attributed to a mechanism based on the interconversion of two enzyme states. One state (E_1), stabilized by Ca^{2+} binding, has the Ca^{2+} sites in high affinity and cytosolic orientation. The alternate state (E_2), stabilized by enzyme phosphorylation, has the Ca^{2+} sites in low affinity and luminal orientation. A more explicit view of the coupling mechanistic can be obtained by considering a minimal number of partial reactions and their equilibrium constants, as follows:

Figure 2 Functional characterization of SR vesicles. (a) Calcium binding at equilibrium in the absence of ATP, demonstrating cooperative binding of two Ca^{2+} per ATPase. (b) The catalytic cycle upon addition of ATP begins with enzyme phosphorylation and inward displacement of the two bound Ca^{2+} . Hydrolytic cleavage of inorganic phosphate (Pi) is the final step of the cycle. E-P, phosphoenzyme. (a) From Inesi G, Kurzmack M, Coan C, and Lewis D (1980) Cooperative calcium binding and ATPase activation in sarcoplasmic reticulum vesicles. *Journal of Biological Chemistry* 255: 3025–3031. (b) From Inesi G, Watanabe T, Coan C, and Murphy A (1978) The mechanism of sarcoplasmic reticulum ATPase. *Annals of the New York Academy of Sciences* 402: 515–534.

where the equilibrium constants (listed after each reaction) relate to conditions allowing constant temperature (25 °C) and pH (7.0).

In the reaction sequence given, the initial high-affinity binding (reaction 1) of two Ca^{2+} activates the enzyme, permitting the use of ATP and the formation of a phosphorylated intermediate (reactions 2–4). In turn, enzyme phosphorylation destabilizes and changes the vectorial orientation of the bound Ca^{2+} , thereby increasing the probability of its

dissociation into the lumen of the vesicles (reaction 5). Note that the equilibrium constant for the enzyme phosphorylation by ATP is nearly 1, indicating that the free energy of ATP is conserved by the enzyme and used to change the Ca^{2+} -binding characteristics. Finally, the phosphoenzyme undergoes hydrolytic cleavage and releases P_i (reactions 6 and 7) before entering another cycle. The reaction sequence shows clearly that the direct mechanistic device for translocation of bound Ca^{2+} is enzyme phosphorylation rather than hydrolytic cleavage of P_i .

The Coupling Mechanism

Free-Energy Use

Because the catalytic and transport cycles are likely to include conformational transitions, it should be noted that such transitions are coupled intrinsically with the chemical reactions subjected to experimental measurement and that their influence is reflected by the equilibrium constants just listed. In fact, the standard free energies ($-RT \ln K$) of the partial reactions add up to the standard free energy of ATP hydrolysis (γ -phosphate), as expected. Most interestingly, the standard free-energy diagram for the partial reactions reveals that the chemical potential of ATP does not manifest itself in the phosphoryl transfer or hydrolytic cleavage reactions (K_4 and K_6 near 1) but rather in the drastic reduction of the enzyme affinity for Ca^{2+} (compare K_1 to $1/K_5$). We can, then, write that, under standard conditions:

$$\Delta G = nRT \ln (K_a^{\text{CaE-P}} / K_a^{\text{CaE}}) \quad [8]$$

per n calcium ions (2 in our case) transported per cycle, and where the equilibrium constant (listed after the reaction) relates to conditions allowing constant temperature (25 °C and pH 7.0). $K_a^{\text{CaE-P}} / K_a^{\text{CaE}}$ are the association constants of the enzyme for Ca^{2+} in the ground state and following activation by ATP. With reference to the reaction scheme given previously, the two relevant constants are K_1 and $1/K_5$. Note that, as written in the scheme and in the forward direction of the cycle, the equilibrium constant for reaction 1 is K_a , while it is K_d for reaction 5.

It is then apparent that the basic coupling mechanism of catalysis and transport consists of the mutual destabilization of Ca^{2+} and phosphorylation sites. Analysis of the amino acid sequence, electron microscopy of ordered ATPase arrays, and diffraction patterns obtained from three-dimensional (3D) crystals have shown that the SERCA enzyme is a 100-kDa protein, folded into a membrane-bound region, an extramembranous (cytosolic) region, and a short stalk between them. The membrane-bound region includes 10 helical segments (M1, ..., M10) and the calcium-binding domain. On the other hand, the extramembranous region or headpiece, comprises the nucleotide-binding (N) domain and a phosphorylation (P) domain, in addition to a smaller actuator (A) domain. It is clear that the Ca^{2+} -binding domain and the catalytic domain are separated by a large distance (~ 50 Å). Therefore, the interconversion of cation-binding and phosphorylation potentials requires a long-range intramolecular linkage, rendered possible by protein conformational changes. It is, then, useful to relate the binding and covalent reactions to

conformational changes that may occur through the catalytic and transport cycles.

Ca^{2+} Binding and Catalytic Activation

Binding of two calcium ions per ATPase molecule is an absolute requirement for enzyme activation. The cooperative character of binding is consistent with a sequential binding mechanism to two interdependent sites (I and II). Spectroscopic studies provided early suggestions of Ca^{2+} -induced conformational effects, accounting for binding cooperativity and enzyme activation. A detailed characterization of the large conformational changes produced by Ca^{2+} binding was then obtained by high-resolution diffraction studies.

The functional role of the Ca^{2+} -induced conformation change lies in its absolute requirement for enzyme activation, rendered possible by the long-range intramolecular linkage. The requirement for Ca^{2+} involves both ATP use for phosphoenzyme formation in the forward direction of the cycle and the formation of ATP upon addition of ADP to phosphoenzyme formed with P_i in the reverse direction of the cycle. Activation is not obtained by Ca^{2+} occupancy of the first binding site only but requires the occupancy of the second site, which may then be considered a Ca^{2+} trigger point for enzyme activation. Ca^{2+} -binding affects directly the M4, M5, and M6 transmembrane helices and is then transmitted to the extramembranous region, resulting in the large displacement of the headpiece domains and catalytic activation. Single mutations of several residues in the segments connecting the Ca^{2+} -binding region with the phosphorylation domain, such as M4, M5, and the M6–M7 loop, interfere with the phosphorylation reactions.

Nucleotide Binding and Substrate-Induced Conformational Fit

Nucleotide protection of the ATPase from digestion with proteinase and the mutational analysis of this phenomenon suggest that ATP binding produces a conformational change that includes repositioning of the A domain, concomitant with approximation of the N and P domains to match the molecular geometry of ATP. This substrate effect appears similar to the approximation of nucleotide binding (fingers) and catalytic (palm) domains that occurs in DNA polymerases. Although ATP is likely to form an initial complex with Mg^{2+} due to the cation-binding property of the nucleotide, ATP and Mg^{2+} reach the catalytic site through a random mechanism. Accordingly, the initial nucleotide binding at the substrate site does not include Mg^{2+} , even though the subsequent phosphoryl transfer and hydrolytic reactions require Mg^{2+} . The stabilization provided by Mg^{2+} to the transition state, relative to that of the enzyme–substrate complex, is of definite kinetic advantage.

Phosphoryl Transfer and Hydrolytic Cleavage

The Ca^{2+} ATPase mechanism includes a covalent intermediate, general acid–base catalysis and metal ion assistance. The covalent intermediate is formed through an attack on the electrophilic ATP terminal phosphate by a nucleophilic carboxylate group (D531) within the catalytic site. The phosphoenzyme intermediate reacts, then, with water to yield P_i .

It is useful to consider the Ca^{2+} ATPase catalytic mechanism in the light of the phosphorylserine phosphatase (PSPase), due to a remarkable structural and functional analogy and the high definition available for the PSPase catalytic intermediates. Based on this analogy, and on ATPase mutational analysis, it appears that the terminal phosphate of ATP comes in close proximity to Asp351, stabilized by neighboring residues such as K352, T353, G626, K684, and N706. Mg^{2+} is then coordinated by D703, T353, D351, and phosphate oxygen, participating in the transition state and in all subsequent steps. Furthermore, T353 is likely to serve as a general acid for proton donation to the leaving ADP. The same residue then acts as a general base, extracting a proton from nucleophilic water for hydrolytic cleavage of the phosphoenzyme.

Interconversion of Phosphorylation and Ca^{2+} -Binding Potentials

The specific step related to interconversion of phosphorylation and Ca^{2+} -binding potentials is often referred to as the $\text{E}_1\text{P}\cdot\text{Ca}_2 \rightleftharpoons \text{E}_2\text{P}\cdot\text{Ca}_2$, to indicate the transition of an intermediate of high phosphorylation potential and high Ca^{2+} affinity to an intermediate of low phosphorylation potential and low Ca^{2+} affinity. The functional and structural information described so far indicates that small conformational changes occurring in concomitance with ATP use at the catalytic site (phosphorylation trigger point) are amplified and transmitted to the Ca^{2+} -binding domain through a long-range relay mechanism. The inversion of phosphoryl oxygen atoms during the transition state of the phosphorylation reaction and the displacement of residues interacting with these oxygen atoms may be the triggering perturbation. This is then followed by large motions of the headpiece domains, which are transmitted to the Ca^{2+} -binding domain in the membrane-bound region. Accordingly, the ability of headpiece domains to chemically cross-link changes drastically as they are displaced by intermediate reactions of the catalytic cycle.

In conclusion, the transduction mechanism relies on a long-range linkage of transmembrane helices and cytosolic domains, whereby large-scale and mutually exclusive motions are triggered by Ca^{2+} binding at one end and ATP use at the other. This is rendered possible by the ability of the protein to use free energy derived from binding and phosphorylation reactions. The cycle proceeds forward to Ca^{2+} release or in reverse to ATP synthesis, depending on the concentrations of ligands, substrate, and products.

Physiological Implication and Inhibitory Drugs

The SERCA2 isoform of cardiac muscle is subject to physiological regulation by phospholamban (PLB), a 22-kDa pentameric protein undergoing reversible association and dissociation. The PLB monomer interacts with the ATPase at the level of both the membrane-bound and extramembraneous regions of the enzyme. In the presence of PLB, the ATPase activation curve is displaced to a higher Ca^{2+} concentration range. The velocity at nonsaturating Ca^{2+} concentrations is thereby

Figure 3 Ca^{2+} signaling in cardiac muscle cells following electrical stimuli. Size and kinetics of the normal (CT) myocytes signal are strongly altered in adrenergic hypertrophy (PE) due to SERCA protein downregulation, and following exposure to thapsigargin (TG) due to SERCA inhibition. From Prasad AM and Inesi G (2009) Effects of thapsigargin and phenylephrine on calcineurin and protein kinase C signaling functions in cardiac myocytes. *American Journal of Physiology* 296: C992–C1002.

reduced, although the maximal velocity at saturating Ca^{2+} concentrations remains unchanged. This inhibition is reversed when PLB undergoes phosphorylation catalyzed by cAMP and calmodulin-dependent kinases. The phosphorylation-dependent relief of inhibition by PLB is related to the physiological mechanism whereby adrenergic stimuli increase Ca^{2+} storing by SR and improve the contractile performance of the heart muscle *in vivo*.

Experimental and clinical studies have uncovered important aspects of SERCA involvement in cardiac physiology and pathology. In fact, the SERCA protein level is reduced in cardiac hypertrophy, relative to the cardiac muscle augmentation. The consequent impairment of Ca^{2+} signaling then contributes to development of heart failure (Figure 3).

Thapsigargin (TG), a plant-derived sesquiterpene lactone, is a very potent and specific SERCA inhibitor. Although TG is not likely to be a physiologic inhibitor, it is nevertheless an extremely useful experimental tool. TG interferes with all partial reactions of the catalytic cycle and induces stabilization of ordered ATPase arrays, suggesting a general effect on the enzyme. Mutational and structural studies indicate that the TG-binding site resides in a cavity delimited by the M3, M5, and M7 helices near the cytosolic surface of the membrane. It is likely that the presence of TG in this cavity confers structural stabilization to the enzyme, thereby preventing conformational responses to Ca^{2+} binding and phosphorylation reaction, as required for the progression of the catalytic cycle. Specific delivery of TG to neoplastic tissue causes apoptosis and may be useful in cancer treatment. Cyclopiazonic acid is another SERCA inhibitor that may be useful for its specificity and reversibility.

Glossary

EF-hand motif The most common calcium-binding motif that has a helix–loop–helix structure.

HAD superfamily A large family found by Aravind et al. in 1998, which includes P-type ion-transporting adenosine triphosphatases (ATPases), haloacid

dehalogenase (HAD), and phosphoserine phosphatase, among others.

Rossmann fold A supersecondary structure, consisting of a pair of $\beta\alpha\beta$ structures arranged so that at least four β -strands form a single parallel β -sheet flanked by two layers of α -helices.

Architecture of Ca^{2+} -Adenosine Triphosphatase

Sarco(endo)plasmic reticulum calcium adenosine triphosphatase 1a (SERCA1a) consists of a single polypeptide of 994 amino acid residues that constitute three cytoplasmic domains (A, actuator; N, nucleotide binding; and P, phosphorylation), 10 transmembrane helices (M1–M10), and small luminal loops (Figure 1). The A-domain, which includes the N-terminal ~50 residues that form two short α -helices and ~110 residues between the M2 and M3 helices, is the smallest of the three cytoplasmic domains. It works as the actuator of the transmembrane gating mechanism that regulates Ca^{2+} binding and release. The A-domain is connected to the M1 and M3 helices with rather long flexible linkers, the lengths of which are of critical importance. It contains one of the signature sequences $^{181}\text{TGES}$, which plays an important role in dephosphorylation. The P-domain takes a Rossmann fold that consists of a central parallel β -sheets and associated α -helices. It contains the phosphorylated residue Asp351, a Mg^{2+} coordinating residue Asp703, and other critical residues that characterize the P-type ATPase as a member of the haloacid dehalogenase superfamily. The N-domain, a long insertion (~240 residues) between the two parts forming the P-domain, is the least conserved of the three cytoplasmic domains, but contains the residues for adenosine binding (e.g., Phe487) and those critical for bridging adenosine triphosphate (ATP) and the P-domain (e.g., Arg560). The hinge between the N- and P-domains is double stranded and allows a change of 60° in inclination.

Of the 10 transmembrane helices, four of them (M2–M5) have long cytoplasmic extensions (Figure 1). In particular, M5 is 60-Å long and extends from the luminal surface to the end of the P-domain, working as the spine of the molecule. Two (M4 and M6) helices have proline residues at the middle and are partly unwound throughout the reaction cycle. M6 and M7 are far apart and connected by a cytosolic loop (L6/7) of ~20 residues. L6/7 runs along the bottom of the P-domain and is hydrogen bonded to M5 (Figure 1(a)). This loop appears to be very rigid and presumably restricts the movement of the M5 helix. M4–M6 and M8 contain the residues directly coordinating two Ca^{2+} (Figure 2). All helices from M1 to M6 move considerably during the reaction cycle,

whereas M7–M10 helices do not, apparently acting as a membrane anchor. In SERCA1, the middle part of M7 containing a GxxG motif makes a tight couple with M5 and allows the bending of M5. A short helical segment between M9 and M10 appears to serve as a socket for the luminal end of the M2 helix. M7–M10 have a specialized function in each subfamily of P-type ATPases, and are absent in heavy metal pumps. In the Na^+K^+ -ATPase, M9 contributes to the association with the regulatory FXYD protein, whereas M10 to the association of the β subunit.

It is important to note that the cytoplasmic end of M5 is integrated into the P-domain near the phosphorylation site as a part of the Rossmann fold and clamped with the M4 helix through a short β -strand (β_0 and β_7 ; Figure 3). The P-domain is also connected to the M3 helix with critical hydrogen bonds. Thus, the events that occur at the phosphorylation site or Ca^{2+} -binding sites can be mechanically transmitted to the other site.

Transmembrane Ca^{2+} -Binding Sites

SERCA1 has two high-affinity transmembrane Ca^{2+} -binding sites (I and II), which are located side by side near the cytoplasmic surface of the lipid bilayer (Figures 1 and 2). The binding of two Ca^{2+} is, however, sequential and cooperative. Site I, the binding site for the first Ca^{2+} , is located in a space surrounded by M5, M6, and M8 helices, and formed by entirely side-chain oxygen atoms and two water molecules (Figure 2). Asn768, Glu771 (M5), Thr799, Asp800 (M6), and Glu908 (M8) contribute to this site. Site II is nearly 'on' the M4 helix and located ~3 Å closer to the cytoplasmic surface than site I (Figures 1 and 2). The M4 helix is partly unwound (between Ile307 and Gly310) and provides three main-chain carbonyls for coordination (Figure 2). Asn796 and Asp800 (M6) provide one side-chain oxygen, whereas Glu309, the gating residue, provides two to cap the bound Ca^{2+} . No water molecule contributes to site II. This arrangement of oxygen atoms is reminiscent of the classical EF-hand motif. Thus, both sites have seven coordination but of different characteristics. Asp800, on the unwound part of M6, is the only residue that contributes to both sites (Figure 2).

Figure 1 Architecture of Ca²⁺-ATPase and its ion-pumping mechanism. (a) A ribbon representation of Ca²⁺-ATPase in the E1·2Ca²⁺ state, viewed parallel to the membrane plane. Colors change gradually from the amino terminus (blue) to the carboxy terminus (red). Two purple spheres (numbered and circled) represent bound Ca²⁺. Three cytoplasmic domains (A, N, and P), the α -helices in the A-domain (A1–A2), and those in the transmembrane domain (M1–M10) are indicated. M1' is an amphipathic part of the M1 helix lying on the bilayer surface. Docked ATP is shown in transparent space fill. Several key residues – E183 (A), F487 and R560 (N, ATP binding), D351 (phosphorylation site), and D703 (Mg²⁺ binding, P) – are shown in ball and stick. Axis of rotation (or tilt) of the A-domain is indicated with thin orange line. PDB accession code is 1SU4 (E1·2Ca²⁺). (b) A cartoon illustrating the structural changes of Ca²⁺-ATPase during the reaction cycle, based on the crystal structures in nine different states.

Figure 2 Structure of the transmembrane Ca²⁺-binding sites. (a) Atomic model in the E1·2Ca²⁺ state. (b) Cartoons illustrating the binding sites in E1·2Ca²⁺ and E2. Viewed approximately normal to the membrane. Ca²⁺ appears as cyan spheres and water molecules as red spheres. Note that site II Ca²⁺ is exchangeable by conformation change of the E309 side chain in E1·2Ca²⁺. The arrows in (b) indicate the movements of the helices in the transition from E2 → E1·2Ca²⁺. Red circles represent protonation of the oxygen atoms. Dotted lines in (b) indicate hydrogen bonds (pink) and coordination of Ca²⁺ (light green).

ATP-Binding Site

ATP binds near the hinge between the N- and P-domains so that it is able to cross-link the two domains. The adenine ring of ATP is inserted in a hydrophobic pocket in the N-domain,

sandwiched by Phe487 and Leu562 (Figure 3). A hydroxyl of the ribose is stabilized by a hydrogen bond with Arg489, and the β -phosphate with Arg560. In the absence of Ca²⁺, the triphosphate chain of ATP takes a folded conformation with Mg²⁺, and interactions with the ATPase are limited to residues

Figure 3 Structural changes caused by the binding of ATP and Mg^{2+} to the P-domain. The bound metal (small green sphere) is most likely Ca^{2+} rather than Mg^{2+} in the crystal structure. The N-domain in E1-ATP appears transparent. Note that the P-domain is bent (arrows in red broken lines) by coordination of the metal by the γ -phosphate, D351 and D703 (shown in stick model) and that the A-domain tilts because of the inclination of the P7 helix.

in the N-domain. When phosphoryl transfer occurs, the Mg^{2+} bound to ATP is released and the triphosphate chain takes an extended zigzag conformation stabilized further by hydrogen bonds with residues in the P-domain (Figure 3).

Synopsis of Ion Pumping

E2 $\rightarrow$ E1 $\rightarrow$ E1·2 Ca^{2+} : Binding of Ca^{2+}

The state after release of Ca^{2+} into the lumen and after dephosphorylation, namely, the E2 state, is considered to be the ground state of the ATPase (Figure 1(b)). The cytoplasmic headpiece is compact with the N- and A-domains tightly associated with several hydrogen bonds between them, primarily to prevent delivery of the γ -phosphate of ATP to Asp351. The P-domain is free from distortion by bound phosphate. The transmembrane Ca^{2+} -binding cavity is filled with water molecules and all the carboxyl groups there are predicted to be protonated to compensate for the empty space and charge imbalance created by the release of Ca^{2+} (Figure 2(b)). However, this structure can persist only at low pH, apparently because the charge compensation by H^+ is insufficient at pH 7. Although the A- and N-domains are most closely associated in this state, thermal agitation opens the headpiece and releases bound protons into the cytoplasm. Released protons are dissipated away through the SR membrane, placing most of the ATPase molecules, at pH 7, into the E1 state. In E1, the carboxyl groups in the Ca^{2+} -binding cavity are not protonated and, therefore, have high affinity to Ca^{2+} .

ATP can bind to the ATPase in the E2 state with a μM K_d , but delivery of the γ -phosphate to Asp351 is hindered by the closed configuration of the cytoplasmic domains. Yet the

Figure 4 A cartoon illustrating two-step rotation in the processing of aspartylphosphate and luminal gating of the ion pathway. Small arrows indicate the movements of the transmembrane helices. M1–M4 (green) and A1–A3 (yellow) helices are numbered. P-D351 refers to phosphorylated Asp351.

binding of ATP in this state facilitates the transition into E1 presumably by opening the headpiece.

The first Ca^{2+} will enter the binding cavity through improperly formed site II (otherwise it will be trapped there) and binds to site I. This will rotate M6 and position Asp800 properly. The M5 helix will straighten (Figure 1(b)) and alter the arrangement of oxygen atoms in site II to form a higher-affinity-binding site. Finally, the carboxyl of Glu309 side chain will cap site II Ca^{2+} , and the binding signal is transmitted to the phosphorylation site some 50 Å away. Because there is enough space around Glu309, the cytoplasmic gate remains unlocked, and site II Ca^{2+} is exchangeable with those in the cytoplasm (Figure 2(a)). The M1 helix is deeply embedded in the lipid bilayer, stabilized indirectly by the bound Ca^{2+} .

Straightening of the M5 helix breaks the closed configuration of the three cytoplasmic domains to allow more inclination of the N-domain for delivery of the ATP γ -phosphate to Asp351, the phosphorylation residue.

E1·2 Ca^{2+} $\rightarrow$ E1P Transition: Formation of the Occluded State

ATP cross-links the P- and N-domains, so that the γ -phosphate of ATP and a Mg^{2+} (or Ca^{2+}) bind to the P-domain to bend it in two directions (Figure 3). The loop containing Asp703, an absolutely conserved residue in the P-domain, is pulled toward Asp351 by Mg^{2+} binding and, consequently, the P6 and P7 helices. This bending of the P-domain tilts the A-domain, which sits on the P7 helix by $\sim 30^\circ$ (1 in Figure 1(b)). This tilting places strain on the link between the A-domain and the M3 helix. Because the M3 helix is connected to the A-domain at the opposite end of the A-domain to the P7 helix, the movement of the P7 helix is highly amplified. This strain appears to be the driving force for the A-domain rotation in the next step (Figures 1(b) and 4). At the same time, the

M1 helix is pulled up so that the top of the transmembrane part (in particular Leu65; **Figure 2(a)**) fixes the side-chain conformation of Glu309 by occupying the space around it. Thus, the cytoplasmic gate is locked and two Ca^{2+} are occluded in the transmembrane-binding sites. M1 and M2 now form a V-shaped structure, which moves as a rigid body until the end of the reaction cycle, and transmits the movements of the A-domain to other transmembrane helices, primarily the luminal half of M4 (M4L).

Phosphoryl transfer from the γ -phosphate to Asp351 fixes the N-domain in a highly inclined position so that a mechanical couple is formed with the A-domain in preparation for a 90° rotation of the A-domain in the E1P–E2P transition. The interface between the N- and A-domains is different from that in E2, as the phosphate and Mg^{2+} bends the P-domain so that the N-domain inclines in a different orientation (**Figure 3**).

E1P → E2P Transition: Release of Ca^{2+} into the Lumen of SR

Phosphoryl transfer to Asp351 allows the dissociation of adenosine diphosphate (ADP), which triggers the opening of the N- and P-domain interface. The A-domain rotates 90° around an axis $\sim 25^\circ$ inclined from the membrane normal (2 in **Figures 1(b)** and 4) and brings the $^{181}\text{TGES}$ loop of the A-domain deep into the gap between the N- and P-domains above the aspartylphosphate (**Figure 5**). The rotation stops when the Thr181 carbonyl makes van der Waals contacts with the Gly626 C α in the conserved ^{625}TGD motif in the P-domain. This position of the TGES loop is stabilized by several hydrogen bonds, presumably to make the resident time in this state long enough for releasing the bound Ca^{2+} into the lumen of SR. The TGES loop occupies the space where ADP was in E1P–ADP to prevent the binding of ADP and to shield the aspartylphosphate from bulk water, as the Gly182 C α makes van der Waals contacts with the aspartylphosphate (**Figure 5**).

This A-domain rotation causes a 30° change in inclination of the P-domain toward M1, which, in turn, causes a drastic rearrangement of the transmembrane helices M1–M6, including a large downward movement of M4, sharp bending of M5 toward M1 (**Figure 1(b)**), and rotation of M6 (**Figure 2(b)**), which destroy the Ca^{2+} -binding sites. The V-shaped structure formed by the M1 and M2 helices pushes against M4L, opening the luminal gate and releasing the bound Ca^{2+} into the lumen (**Figure 4**). This will allow protons and water molecules to enter and stabilize the empty Ca^{2+} -binding sites (**Figure 2(b)**).

In the conversion of the A-domain rotation to the downward movement of the M4 helix, the wedge shape of the P-domain and the flexible link between the A-domain and the M1 helix (**Figure 1(a)**) play a critical role.

E2P → E2 Transition: Hydrolysis of Aspartylphosphate and Closing of the Luminal Gate

In the E2P → E2•Pi transition, the A-domain rotates further by 25° around an axis near Thr181, different from the previous one (3 in **Figures 1(b)** and 4). This rotation places further strain on the M2 helix, which, as a result, partly unwinds and releases the V-shaped structure formed by the M1 and M2 helices so that it takes a $\sim 5\text{-}\text{\AA}$ lower position toward the

luminal side. This movement imposes more upright position on M4L and closes the luminal gate.

This rotation of the A-domain is related to the introduction of one water molecule in the phosphorylation site. Glu183 in the TGES loop now fixes the water molecule and catalyzes its attack on the aspartylphosphate, presumably by withdrawing a hydrogen from the water molecule (**Figure 5**). Then, the inorganic phosphate and Mg^{2+} are released and the P-domain becomes relaxed. This, in turn, releases the M1 and M2 helices to lock the luminal gate and places the ATPase into the E2

Figure 5 Phosphorylation site in the E2P ground and E2 ~P transition states. BeF_3^- and AlF_4^- are phosphate analogs of the ground state and transition state, respectively. Secondary structure motifs are superimposed on the atomic models. Conserved sequence motifs are labeled. Water molecules appear as small red spheres. Dotted lines represent hydrogen bonds and coordination of Mg^{2+} . Double-headed arrow in E2P shows that Gly182 C α and aspartylphosphate form van der Waals contacts. The white circle in E2 ~P identifies the water molecule attacking the aspartylphosphate.

state. The top amphipathic part of M1 (M1') forms a part of a cytoplasmic access funnel leading to Glu309, the side chain of which becomes stabilized by hydrogen bonding with Asn796 (Figure 2(b)). By release of protons to the cytoplasm, Glu309 is supposed to change the side-chain conformation and catch Ca^{2+} .

Summary

As described, Ca^{2+} -ATPase undergoes a series of very large movements of the cytoplasmic domains and rearrangements of the transmembrane helices. Such large movements are necessary to cope with thermal fluctuations and yet to utilize thermal energy effectively for ion pumping. The P- and N-domains change interfaces and thereby control the orientation of the A-domain, the actuator of transmembrane gates. ATP, phosphate, Mg^{2+} , and Ca^{2+} are the modifiers of the interfaces (Figure 1(b)). Here, ATP works as a cleavable cross-linker of the N- and P-domains. Free energy provided by the hydrolysis of ATP is used in a very implicit way. It seems that the overall reaction is made possible by suppressing backward reaction and ATP works as a loose coupler that connects thermal energy and electrochemical work.

Atomic coordinates of the aligned structures, movies on the structural changes during the reaction cycle, and some results of molecular dynamics simulations are available on the Internet.

Glossary

Actin Protein active in muscular contraction, cellular movement, and maintenance of cell shape. Actin can be in either globular (G-actin) or filamentous (F-actin) form.

Cytoskeleton Three-dimensional network of scaffolding proteins that provides internal support for cells, anchors internal cell structures, and functions in cell movement and division.

Dictyostelium discoideum Soil-living migratory amoeba that transitions from a group of unicellular amoebae into

a multicellular organism composed of spores atop a stalk of vacuolated cells.

Myosin Motor protein that combines with actin to form actomyosin, a contractile complex.

Neutrophil The most abundant white blood cell and key player in innate immunity.

Polarity The asymmetric organization of cellular components and structures.

Pseudopod Temporary cellular protrusion process that functions during migration.

Introduction

Directed cell migration in response to external chemical gradients, or chemotaxis, is of fundamental importance in many physiological and pathological processes. For example, in mammals, chemotaxis plays a key role in embryogenesis, tissue maintenance, and the immune response, and has also been implicated in metastasis, arthritis, and asthma. Different cell types display distinct migration behaviors depending on the strength of adhesion forces they impose on neighboring cells and/or on the surfaces on which they migrate. This, in turn, affects the shape of the cells and the speed at which they move. Mesenchymal migration is characterized by strong cell–substrate adhesion forces, which give rise to relatively slow migration speeds and low cell deformability. On the other hand, amoeboid motion is characterized by relatively few and weak cell–substrate adhesions, greatly deformable cell shapes, and fast motion (often reaching in excess of $10\ \mu\text{m min}^{-1}$). In this article, we describe the signal transduction mechanisms that regulate amoeboid-like motion as displayed by neutrophils and the soil-dwelling amoeba *Dictyostelium discoideum*, two systems that use common molecular mechanisms to sense chemical gradients.

During chemotaxis, both *Dictyostelium* and neutrophils are able to transduce shallow external chemical gradients into a highly polarized shape consisting of F-actin rich pseudopods at the front and myosin II contractions at the back, leading to cell elongation and directional migration. The sensing abilities of these cells are impressive, as they can (1) detect and respond to an external gradient as small as 2% across their length and (2) follow gradients that are rapidly changing in time. Many signaling molecules involved in this process have been identified through decades of research; however, motion is a space- and time-dependent process. Therefore, knowledge of the spatio-temporal dynamics of these molecules is of critical importance. Aiding in our understanding of this process is the fact that, to a large extent, the chemical gradient-sensing abilities of cells can be decoupled from their cytoskeletal polarities and motion capabilities. This allows a detailed investigation of each part of the chemotactic system independently.

Gradient Sensing

The first step in the chemotaxis response is the sensing of an external chemical or chemoattractant (Figure 1). In establishing polarity, the up-gradient side of the cell determines the front or leading edge, and the down-gradient side determines the back or trailing edge. In both neutrophils and *Dictyostelium*, gradient sensing is transmitted through transmembrane G-protein-coupled receptors (GPCRs). These receptors are associated with internal membrane-bound heterotrimeric G proteins containing α , β , and γ subunits. The binding of chemoattractants to GPCRs induces a conformational change that results in the dissociation of the coupled G proteins into G α and G $\beta\gamma$ subunits, which activate a wide array of downstream effectors (Figure 1). The fundamental question is: how do biochemical signals transduce external chemical gradients into highly polarized responses and migration? It has been shown that GPCRs and G proteins remain uniformly distributed on the plasma membrane during chemotaxis (Figure 2) and that the distribution of chemoattractant-bound GPCRs closely matches the external gradient. These findings show that signals downstream of receptor binding and G-protein dissociation lead to a polarized morphology.

In both *Dictyostelium* and neutrophils, chemoattractant stimulation of GPCRs leads to the rapid activation of Ras, which, in turn, activates phosphatidylinositol 3 kinase (PI3K). Activated Ras is the most upstream molecule identified to date that is localized primarily at the front of chemotaxing cells, indicating that the onset of polarity occurs between G proteins and Ras activation (Figure 2). Once activated, PI3K converts membrane-bound phosphatidylinositol-4,5-bisphosphate (PIP₂) into phosphatidylinositol-3,4,5-trisphosphate (PIP₃). PIP₃ acts as a membrane-docking site for molecules containing pleckstrin homology (PH) domains, such as Akt/protein kinase B (PKB), as well as nucleotide exchange factors for Ras (such as RasGEFs), and other small GTP binding proteins. These molecules in turn recruit actin polymerization/stabilization proteins to the front of cells, leading to pseudopod extension. While this pathway has been viewed for many years as the key gradient-sensing pathway,

Figure 1 The chemotaxis signaling pathway. (Top) Scheme showing a polarized cell in a chemoattractant gradient. The front of the cell is oriented toward the higher concentration of chemoattractant. The black arrow indicates the direction of motion. (Bottom, left) At the front of the cell, GPCR activation initiates an intracellular signaling cascade that results in actin polymerization and pseudopod protrusion. The PI3K pathway, in which PIP₂ is converted into PIP₃, is shown in detail; other pathways are explained in the text and are not shown. (Bottom, right) At the back of the cell PIP₃ signaling molecules are converted back into PIP₂. In addition, further molecules are recruited to cause actomyosin contraction leading to retraction of the cell back. Note that the pathways at the cell back are only now becoming understood and, therefore, no links are drawn between the components.

Figure 2 Fluorescence images depicting the cellular distribution of various GFP-labeled signaling components during chemotaxis. The up-gradient side is depicted by the stars. Ras is the most upstream molecule in the chemoattractant-sensing cascade to display spatial localization. From Comer FI and Parent CA (2002) PI3Kinases and PTEN: How opposites chemoattract. *Cell* 109: 541–544.

recent work in *Dictyostelium* has indicated that other effectors may be acting in parallel. These include phospholipase A₂ (PLA₂), guanylyl cyclase (GC), and target of rapamycin complex 2 (TORC2). Interestingly, these pathways may not have identical roles. For example, the PI3K pathway has been proposed to specifically confer sensitivity to shallow extracellular

gradients as PI3K-inhibited cells can still perform chemotaxis toward steep gradients.

In *Dictyostelium*, the phosphoinositide 3' phosphate phosphatase (PTEN), which de-phosphorylates PIP₃ into PIP₂, is recruited at the back and side of chemotaxing cells. This further ensures that PIP₃ is localized exclusively at the cell front,

effectively eliminating the binding and activation of PH domain-containing proteins at the back and sides. Cells lacking PTEN have multiple fronts and exhibit severe chemotaxis defects. In neutrophils, genetic knockout of the phosphoinositide 5' phosphate phosphatase (SHIP1), which also dephosphorylates PIP_3 , leads to unregulated PIP_3 levels and chemotaxis defects. SHIP1 therefore acts homologously to PTEN in these cells. The phosphorylation state of $\text{PIP}_2/\text{PIP}_3$ can therefore be viewed as an effective means to determine the gradient-sensing state of a cell (Figure 2).

Cytoskeletal Polarization

The gradient-sensing machinery described in the previous section drives directed migration by regulating where specific cytoskeletal elements should be active (Figure 1). For both *Dictyostelium* and neutrophils, signals downstream of PIP_3 bring the suppressor of cAR1 (SCAR)/Wiskott-Aldrich syndrome protein (WASP)-family verprolin homologous protein complex to the cell front. This complex then recruits Arp2/3, an actin-binding protein complex that promotes the nucleation of new actin filaments and pseudopod extension. In the back of the cell, actomyosin complexes are assembled and regulated by a variety of proteins (RhoA, ROCK, and PDZ/RhoGEF in neutrophils; PAKa and cGMP in *Dictyostelium*), and myosin-II based contraction pulls the back of the cell forward. These structures do not form in the front of cells, ensuring that contraction moves the entire cell forward.

Intiguently, cells with an already highly polarized cytoskeleton tend to have enhanced polarization of signaling molecules, with sharp distinctions between front and back. Indeed, an elongated cell, through its increased surface area, can better sample the external chemoattractant environment than a rounded cell, leading to better chemotaxis. In addition, there are positive feedback loops between gradient sensing and cytoskeletal proteins – that is, gradient-sensing molecules drive cytoskeletal polarization, which in turn further enhance the spatial localization of front and back signaling molecules. Exactly how this feedback is achieved is not known. One possibility is that cytoskeletal polarity stabilizes the gradient-sensing molecules; another is that polarity actually drives further recruitment. Importantly, the stimulation of cells with a uniform dose of chemoattractant can cause cells to polarize and randomly migrate (a process referred to as 'chemokinesis') in the absence of an external gradient. This further shows that the polarization of the cytoskeleton is not strictly dependent on the gradient-sensing machinery detecting an external gradient.

Finally, the role of the environment on chemotaxis is now beginning to be understood. Most chemotaxis experiments are carried out on simple two-dimensional (2D) surfaces, such as agar or glass for *Dictyostelium* and collagen or fibronectin for neutrophils. These types of substrates are, in many cases, an oversimplification of the types of three-dimensional (3D) environments that amoeboid cells encounter in their natural settings. It has been shown that patterning a 2D surface, either chemically or with physical etching, can itself direct migration. Recent work has also shown large differences in cell morphology between migration in 2D and 3D environments, and it

is becoming clear that various signaling pathways can play critical roles depending on the type of environment encountered. For example, neutrophil migration through a tight 3D matrix depends on one type of PI3K ($\text{PI3K}\gamma$) that is not as critical for 2D surface migration.

Mathematical Models

Although many of the key players regulating chemotaxis have been identified, a thorough understanding of the system requires knowledge of the timescales, binding rates, binding locations, and regulation of each of the molecules. To clarify this process, mathematical modeling has been used to determine if experimentally observed cell behavior can be entirely understood using known molecules and their spatiotemporal dynamics. This approach has many advantages, including suggesting quantitative experiments, classes of new molecules to look for, or even what measurements to take. By bringing together the approaches of quantitative experimental biology

Figure 3 Schematic representation of mathematical models for gradient sensing. Cells (round) are exposed to either a uniform stimulus (left column) or a gradient (right column). The resulting spatial intracellular stimulation level of the cell is shown in red. In the pilot pseudopod model, cells detect a gradient by extending small pseudopods that sense a temporal change in chemoattractant receptor occupancy. In the pseudopod-centric model, stimulated cells continually extend large pseudopods, and in a gradient the internal sensing machinery biases the location of new pseudopods. In both of these models, a uniform stimulus does not change cell behavior. In the local excitation, global inhibition (LEGI) model, the response of the cell to a uniform stimulus is initially along the periphery but diminishes with time. In a gradient, the response matches the strength of the external gradient. In the positive feedback model, the cell has a region of strong excitation. When uniformly stimulated, this region is randomly located, whereas in a gradient it follows the direction of, but is much stronger than, the external gradient.

and mathematical modeling, researchers will eventually be able to fully understand the gradient sensing and motility networks of chemotaxing cells (see [Box 1](#) for an overview of how to measure various migration metrics).

Current mathematical models of gradient sensing generally follow the PI3K pathway and model the cell as a 2D circular object. [Figure 3](#) illustrates some of these mathematical models. One model is the pilot pseudopod model, where a cell continuously extends small pseudopods in many directions, only keeping and enlarging those that experience an overall positive change in chemoattractant-bound receptor. While this can account for motion in response to a gradient, it does not explain the observed enrichment of PH domain-containing proteins at the front of cells treated with agents that inhibit pseudopod formation. A pseudopod-centric model has also been proposed, where a cell continually extends large pseudopods and chemotaxes, but it biases the formation of new pseudopods with its gradient-sensing apparatus. This model also does not properly

account for all chemotactic behavior. It does not explain the absence of migration when no chemoattractant is present, although it is possible that the motion cycle has to be activated by the addition of chemoattractant.

To address the gradient-sensing experimental findings, the local excitation, global inhibition (LEGI) model has been proposed. In this model, there are two chemical species: one is a stationary membrane-bound excitation molecule that is quickly activated by the binding of chemoattractants to GPCRs; the other is a diffusible slowly activating global inhibitor whose concentration is set by the average cell exposure to chemoattractants. A uniform stimulus of chemoattractant causes a rapid activation of the excitation molecule all around the cell periphery, which is dampened by the slow activation of the inhibitor molecule, which eventually deactivates the excitation molecule back to baseline. A steady gradient of chemoattractant, however, causes the excitation molecule to be more active at the front, while the inhibitor is present

Box 1 Metrics of Chemotaxis

There are several quantitative metrics that measure the ability of cells to perform chemotaxis. Often these metrics are used to determine the phenotype of a mutant in which a signaling pathway component has been suppressed or overexpressed. The metrics fall broadly into two types: center-of-mass and shape.

Center-of-mass statistics focus on the translocation of the center of a cell as it migrates (a). Such metrics are relatively easy to compute and understand; the center of a cell is followed in time as it moves, and various questions can be asked about its trajectory. Some software packages exist to automate the tracking of cell centers. One metric of motion is the speed of a cell, and another is the chemotaxis index, which is a measure of the fidelity with which a cell moves up a chemotactic gradient. Both speed and chemotactic index can be measured instantaneously (i.e., from one image frame to the next) or as a track total (i.e., from the start point to the end point). Instantaneous measures, if taken over too small a time, suffer from large uncertainties induced by the imaging noise and/or small variations in the center-finding procedure. Measures using only the start and end points of the tracks are less sensitive to noise but generally underestimate the speed and miss details in the chemotactic index. Other noninstantaneous metrics can also be useful. One example is the persistence of a cell's path, which measures the wiggleness or randomness with which a cell moves. This metric is less susceptible to noise as it involves a cell's entire path. However, it is still important to have enough data points to avoid overestimating the persistence. Therefore, for center-of-mass metrics, choosing an appropriate time frame for measurement is essential.

Shape metrics generally ignore overall cell motion and instead focus on how a cell's membrane deforms in time (b). These metrics tend to be more complicated and harder to compute, as they require accurate tracing of the membrane edge, though various software packages exist to assist in this process. A cell's overall shape and polarization (as measured by its circularity) are one metric, and another is the curvature of the membrane at every membrane point. These metrics can also be measured as functions of time, giving timescales for the cell's motion cycle. The location and time dynamics of protrusions and retractions are two important metrics. Finally, a powerful technique is to correlate shape behaviors with the spatiotemporal dynamics of fluorescently tagged gradient-sensing or cytoskeletal components, allowing further dissection of the chemotaxis process.

equally everywhere. This leads to net excitation at the front of the cell and net inhibition at the cell back (**Figure 3**). While Ras or PI3K can play the role of the local exciter, a candidate molecule for the global inhibitor has yet to be identified. This model is able to explain how cells treated with actin polymerization inhibitors are capable of sensing external gradients. However, it is not able to address how shallow external gradients are transduced into highly polarized responses (**Figure 2**), as the excitation in this model is proportional to the external gradient. Adding positive feedback loops via actin-binding proteins can introduce amplification of the chemotactic signal, but this causes spontaneous activation problems as well as insensitivity to changing gradients. Many other types of models exist but, in short, no single model has been able to accurately capture all of the complex dynamics cells display during chemotaxis. Most likely, a mix of the above models will accurately explain the biology of chemotactic sensing and motion.

Glossary

Cell cycle or cell division cycle Refers to the four sequential stages (G1, S, G2, and M) that are repeated in each cell division.

Cyclin-dependent kinases (CDKs) Phosphorylation enzymes whose activities are specified by their cyclin partners, which are periodically synthesized in the cell division cycle.

DNA polymerases Enzymes that join nucleotides together via phosphodiester bonds in a template-dependent manner.

Lagging strand Template for the DNA strand that is synthesized discontinuously due to the polarity of DNA polymerases.

MCM helicase Eukaryotic counterpart of the DnaB helicase of prokaryotes. It is a ring-shaped structure consisting of six nonidentical but highly conserved subunits (Mcm2, -3, -4, -5, -6, and -7) that encircles and unwinds DNA at the replication fork.

Okazaki fragments Short DNA fragments of about 200 nucleotides (~2000 nuc in bacteria) synthesized on the lagging strand in a polarity opposite to the unwinding of the replication fork.

Proofreading Refers to the editing function of the 3' to 5' exonuclease activity that removes mispaired nucleotides as they are being incorporated. It is associated with DNA polymerases that synthesize the bulk of the genomic DNA to provide accuracy to the copying mechanism.

Of the numerous DNA polymerases that replicate and repair DNA in eukaryotic cells, polymerase α -primase (Pol α) is the only enzyme capable of *de novo* DNA synthesis. This unique property is essential for initiating DNA synthesis in providing the primers for leading- and lagging-strand synthesis. The priming of Okazaki fragments in lagging-strand DNA synthesis is critical for coordinating DNA replication with repair and cell-cycle progression. Pol α has also been implicated in other cellular processes such as telomere metabolism, sister chromatid cohesion, and epigenetic regulation of nucleosome structure for transcriptional silencing. The article focuses on the roles of Pol α at DNA replication forks.

Structure and Enzymatic Function

Pol α is composed of four subunits of 180, 68, 58, and 48 kDa according to their molecular mass in SDS gel. In yeast, all four subunits are essential for viability and the basic 4-subunit structure is conserved in all eukaryotes. The largest 180-kDa subunit can be divided into three domains each with a specific function. The central domain encodes the catalytic DNA polymerase activity and the C-terminal domain is responsible for the subunits assembly. Consistent with the many functions of Pol α , the N-terminal domain has been shown to interact with several factors/structures with unrelated functions including Mcl1(And1/Ctf4), PP2A, concanavalin A, SV40 large T antigen, and Mcm10. The smallest p48 has the primase activity that synthesizes short RNA primers *in vitro*. However, the full primase activity requires p48 to be in a complex with p58. p68, also known as the B subunit, which regulates the nuclear activity of Pol α , is phosphorylated by cell-cycle-dependent kinases and its interaction with p180 is important for the nuclear import of the polymerase.

An important feature of the 4-subunit complex is that both catalytic activities are involved in initiating DNA replication by the synthesis of a chimeric 5' RNA–DNA 3' primer (Figure 1). The transition of RNA to DNA synthesis involves the initial synthesis of 7–10 bases of RNA oligonucleotide by the primase (p48), followed by an extension of the RNA primer by the DNA polymerase activity of the p180 subunit to 30–40 nt. The switch between the RNA primase and the DNA polymerase activity within Pol α is believed to be regulated by the unit length of the primer acting as a termination signal. The tight association of the primase and DNA polymerase within the same protein complex facilitates direct transfer of the RNA 3' end to p180 without dissociation from template.

In eukaryotes, replication initiates from certain sites on the chromosomes where the prereplication complex is assembled. Upon cell-cycle-dependent cues, unwinding of the DNA and assembly of the elongation complex occurs, signaling the start of DNA replication. At the leading strand, Pol α synthesizes the primers for extension by DNA polymerase ϵ . However, lagging-strand synthesis is more complex. The RNA polymerase activity of Pol α initiates synthesis of the primers that are completed by the DNA polymerase activity. Further elongation of the Okazaki fragments is achieved by a switching of polymerases from Pol α to Pol δ mediated by replication factor-C (RF-C) and replication protein A (RPA). Pol α is a low-fidelity enzyme with an incorporation error rate of 10^{-4} – 10^{-5} compared to the error rates of 10^{-6} – 10^{-7} of the main replicative DNA polymerases, Pol δ or Pol ϵ . As a result, primers synthesized by Pol α on the lagging strand are mutagenic if not removed. This problem is circumvented by the proof-reading property of Pol δ , which interacts with Pol α and collaborates with FEN1 and DNA ligase to remove the primers during the maturation of Okazaki fragments.

Figure 1 A model for the interaction between Pol α and the MCM helicase through the linkage of other factors such as Mcm10 and And1 on the lagging strand at the replication fork. The MCM helicase is a double hexamer with the N-terminal domains organized in a head-to-head configuration. Not shown are other polymerases of the replisome (shaded gray) such as Pol δ and Pol ϵ and the associated factors on the leading strand.

Though the main role of Pol α is to carry out DNA replication, there is evidence that Pol α has other roles. In conditional mutants of p180 and p48 subunits, replication of the chromosomal DNA is impaired, but DNA is still synthesized at the restrictive temperature. In addition to phenotypes such as increased mutation rate (measured by mitotic recombination, gene conversion, excision of large inverted regions, spontaneous mutations, etc.) and sensitivity to alkylating reagents, some Pol α mutants affect telomere length. Other mutants of Pol α are defective in localization of the major heterochromatin protein Swi6 at centromeres and telomeres suggesting a role for Pol α in epigenetics. Likely, the function of Pol α is not limited to DNA replication, but may include a broader role in chromatin biology.

Regulation of Pol α Activity

In budding yeast, the genes encoding the Pol α subunits are transcribed at the G1/S boundary. However, the protein subunits are stable as the cells are able to undergo several divisions after inhibition of new Pol α synthesis. Therefore, the initiation of DNA synthesis at the beginning of S phase is unlikely to be regulated by fluctuations in the Pol α level. However, cell-cycle-dependent phosphorylation of the two largest subunits has been observed at different stages of the cell-division cycle suggesting that the cell-cycle-dependent activity of Pol α may be regulated by posttranslational phosphorylation. Consistent with this idea, Pol α from human cells has the greatest capacity to replicate SV40 DNA when it is purified during the G1/S transition and this activity decreases as the cells reach G2/M. Furthermore, in human cells, p180 and p68 are phosphorylated by cyclin-dependent kinase (CDK) kinases

during the G1/S and G2/M transitions. In the fission yeast, p180 is phosphorylated during S phase. In the budding yeast, p68 is phosphorylated during the G1/S transition and dephosphorylated as the cells exit mitosis. The phosphorylation event, concomitant with RNA synthesis by Pol α , is dependent on the activation of the MCM helicase, melting of the origin DNA, and recruitment of topoisomerase I, Cdc45, and RPA, culminating in the initiation of DNA replication.

The cellular level and integrity of Pol α are critical for genome stability. Aberrant mutant activity causes chromosomal damage such as DNA breaks as well as changes in telomeric length and chromatin structure. Reduced level of Pol α results in elevated chromosome translocation and loss. Proper binding of p180 to p68 is required for nuclear localization, and misfolded p68 or p180 is barred from nuclear entry because of altered interaction. Consequently, misfolded Pol α is sequestered in the cytoplasm and channeled for proteasome-dependent degradation.

Pol α and the Helicase

The two main molecular motors in the replication elongation machinery are the DNA polymerases and the helicase. Coordination of these two activities on both the leading and lagging strands is important for the simultaneous replication of both strands as well as the prevention of excessive single-strand exposure due to unwinding. Moreover, coupling of the helicase and Pol α on the discontinuous strand ensures the proper spacing and timing for the *de novo* synthesis of Okazaki primers. The importance of an intimate association between primase and helicase activity is best illustrated in bacteriophage and prokaryotes. In bacteriophage T7 and p4, the primase and helicase are encoded in a single polypeptide. In *Escherichia coli*, the primase (DnaG) and helicase (DnaB) interact to form a complex. This interaction stimulates both the primase and helicase activities and relaxes the sequence specificity of DnaG, allowing DnaG to successively prime Okazaki fragment synthesis during lagging-strand synthesis. The hexameric DnaB helicase forms a ring structure that encircles the 5' lagging strand as it translocates and unwinds, while DnaG uses the newly exposed single-stranded DNA (ssDNA) as template. The topological linking of the helicase to DNA enhances processivity of the helicase and facilitates translocation of the primase to the priming sites.

In eukaryotes, the MCM helicase is considered the main replicative helicase. Like DnaB, the MCM helicase is a hexameric enzyme that forms a ring structure, but unlike DnaB the six subunits are nonidentical though highly conserved. The MCM helicase is loaded onto duplex DNA as a double hexamer, encircling the duplex DNA suggesting that the unwinding mechanism may be different from that of DnaB. It has been proposed that the MCM helicase may act as a double-strand DNA translocase that pumps duplex DNA into the double hexamer in a manner analogous to that of the SV40 large T antigen or the bacterial RuvAB Holliday junction branch-migration enzyme (Figure 1). Under this scenario, connecting the MCM helicase that is positioned ahead of the fork on the duplex DNA with Pol α that initiates on the unwound single strand must rely on other factors. Indeed, direct interaction

between Pol α and the MCM helicase has not been observed. A candidate for the linker protein is Mcm10 in budding yeast, which is required for both the initiation of DNA synthesis at the G1 to S phase transition and throughout the elongation process. Mcm10 interacts with both Pol α and MCM helicase and is required for Pol α stability in the budding yeast and humans (Figure 1). Interaction between the subunits of the MCM helicase and Mcm10 has been confirmed in *Xenopus*, and physical interaction between human Pol α and Mcm10 has been determined by crystallography. In *Xenopus* and humans, the cohesion establishment factor Ctf4/And1 also interacts with Pol α . Furthermore, interaction with RPA and Ctf4/And1 stimulates the primase activity and renders the enzymes more processive.

Coordinating DNA Replication with Checkpoint Response

The surveillance of vital cellular processes and the coordination of their ordered progression are important functions of the checkpoint pathways in eukaryotic cells. Under DNA replication stress or in the presence of DNA damage, the S-phase checkpoint system ensures the integrity of the replication fork and the proper firing of origins by delaying S-phase progression and by preventing exit from mitosis. The S- and G2/M-phase delay facilitates DNA repair and stress recovery. The key players in the budding yeast S-phase checkpoint pathway are Mec1 and Rad53 and the main replication stress signal that activates the checkpoint is thought to be RPA-coated ssDNA. The exposure of ssDNA occurs when unwinding of the double-stranded DNA by the helicase continues while the polymerase stalls. Inhibition of DNA synthesis as a result of checkpoint activation is important and many lines of evidence suggest that Pol α may be involved. The *pri1-M4* primase mutant is defective in DNA damage response and other Pol α mutants display synthetic lethality with mutations in the key checkpoint genes. These observations suggest that Pol α may function in coupling DNA replication to checkpoint activation as well as serving as one of the final targets of the checkpoint pathway. This scenario is conceptually attractive as inhibition of the primase activity due to DNA lesion will slow down replication and allow repair. Failure to do so will increase mutation rates. However, Pol α is not a direct target of Rad53, but rather, it is suggested that ssDNA-bound RPA, which physically interacts with Pol α , may be the mediator that transduces the signal from Rad53 to Pol α .

In addition to its role in initiation of DNA synthesis, RNA primers may also function in checkpoint activation as the type of chromatin structure required for checkpoint activation included the synthesis of an RNA primer. Specifically, DNA unwinding, Pol α loading, and RNA synthesis, but not new DNA synthesis, are required for intra-S-phase checkpoint activation. Blocking primase activity by the use of primase inhibitors or by utilizing Pol α mutants defective only in RNA synthesis inhibited replication but did not induce checkpoint activation. This observation suggested that RNA primer, in addition to RPA-coated ssDNA, is a component of the signal for checkpoint activation.

A detailed mechanism of how stalled forks are sensed by the Ataxia Telangiectasia-mutated and Rad3-related (ATR)

(homolog of Mec1) pathway remains to be understood, but Pol α seems to play an important role in providing the substrate for the activation of the ATR pathway (Figure 1). Tethering ATR to RPA-coated ssDNA through interaction with ATR interacting protein (ATRIP) is required for ATR activation. However, recruitment of ATR to RPA ssDNA is not sufficient, TOPBP1 (Mus101/Rad4/ Cut5/Dpb11) and 9–1–1 (Rad9, Rad1, Hus1) complex are also required. TOPBP1 has an ATR activation domain that interacts with both ATR and ATRIP and stimulates ATR kinase activity. This ATR activation requires the interaction of TOPBP1 with Rad9. It has been suggested that 9–1–1 helps to position TOPBP1 to stimulate ATR kinase activity. The current model for checkpoint activation is that under replication stress RPA-coated ssDNA recruits ATR–ATRIP, while 9–1–1, loaded onto DNA, associates with TOPBP1, and facilitates the activation of ATR–ATRIP–RPA. The role of Pol α in this process is to recruit TOPBP1 and the 9–1–1 complex by providing a specific chromatin substrate for 9–1–1, which specifically binds 5' DNA junction. Primer synthesis by Pol α creates just such a structure. The idea that persistent primers are the direct targets of ATR activation is corroborated by the observation that primer synthesis is required for checkpoint activation. These observations paint an intricate relationship between primer synthesizing activity on the lagging strand and checkpoint surveillance.

The vital role that Pol α seems to play at the fork during elongation suggests a possible advantage in having a discontinuous lagging-strand synthesis composed of multiple Okazaki fragments. The persistent presence of Pol α at the fork places Pol α in a position to directly regulate DNA synthesis on the lagging strand. As one of the final targets of checkpoint activation Pol α is poised to coordinate DNA replication with checkpoint surveillance. However, this important role would require the coordinated modulation of both primase and helicase activity because uncoupling of the two motors would exacerbate ssDNA exposure. Unlike the leading strand where DNA unwinding is immediately followed by DNA synthesis, lagging-strand synthesis involves significant exposure of unwound ssDNA for retrograde primer synthesis by Pol α . Therefore, modulation of Pol α alone or uncoupling of the helicase and primase activity of the lagging strand would present an increasingly dire situation for recovery. As the level of checkpoint activation increases with the amount of ssDNA accumulation this uncoupling would further stimulate checkpoint activation. To compensate, additional modifications of the helicase to slow down DNA unwinding or alternative mechanism of coupling the primase and helicase would be required under replication stress. Accordingly, MCM helicase subunits are phosphorylated by the checkpoint pathway during replication stress conditions. In the budding yeast, Pol α is destabilized in the conditionally lethal *mcm10-1* mutant presumably as a result of an unrestrained helicase activity that leads to extended exposure of ssDNA and collapse of the replication fork. A recent study showed that suppressor mutations in Mcm2, which compromise the MCM helicase activity, reduce ssDNA exposure and stabilize Pol α suggesting that fork stability is restored. In addition to the suppressor mutation in the MCM helicase, stabilization of Pol α requires the function of the Mec1 checkpoint protein suggesting that Mec1 provides an alternative mechanism for stabilizing the replication fork

under replication stress. The dynamic relationship between the replication and checkpoint factors underscores the measures that eukaryotic cells must take to provide a failsafe mechanism for keeping Pol α and the MCM helicase intact at the fork for the resumption of DNA synthesis once repair is complete.

Structure

Catalytic Subunit

Pol δ is a multisubunit complex, consisting of a catalytic subunit, and, depending on the organism, two or three accessory subunits (Table 1). The catalytic subunit is essential for yeast cell growth and belongs to the B-family of DNA polymerases found in all three kingdoms of life.

The simplest B-family DNA polymerase is the replicative DNA polymerase of bacteriophage RB69. Its structure shows three distinct domains: a large N-terminal domain, the 3'-exonuclease domain, and the polymerase domain. The polymerase domain shows a structure that is typical for DNA polymerases with the template primer junction and the dNTP binding into a broad cleft that closes up into a closed complex prior to the chemical polymerization step. The single-stranded template DNA enters the active site from a cleft situated between the N-terminal domain and the exonuclease domain, whereas the double-stranded DNA exits the active toward the bottom in Figure 1(a). The active site of the polymerase domain is precisely defined to promote favorable binding of that incoming dNTP that will form a proper Watson–Crick base pair with the next template nucleotide to be replicated, whereas non-Watson–Crick base pairs show a poor fit and are, therefore, disfavored. These geometric considerations, together with the favorable energetics obtained from Watson–Crick base pairing, result in a high fidelity of replication. Yeast Pol δ has an error rate of about 10^{-4} – 10^{-5} , that is, there is one misincorporation event for every 10^4 – 10^5 nucleotides (nt) replicated. The fidelity of DNA replication by Pol δ is enhanced about 10-fold through proofreading by its 3'-5'-exonuclease activity.

The 3'-exonuclease domain of Pol δ belongs to the same class as those identified in other proofreading DNA polymerases. Two divalent metals in the exonuclease domain coordinate with aspartates/glutamates to orient a water molecule as a metal-hydroxide ion for attack of the internucleotide phosphodiester bond to be cleaved. The active site of the 3'-exonuclease domain is ~ 35 Å distant from the active site of the polymerase domain. Misincorporation by the polymerase results in stalling of further DNA synthesis because of a poor geometric fit of the mismatched template–primer junction in the active site of the polymerase domain. This stalling promotes dissociation of the primer terminus from the polymerase domain and binding in the exonuclease domain. Although it is yet unclear how this translocation from the polymerase to the exonuclease domain occurs, it is an important step in maintaining replication fidelity, and it is just as important that this translocation is reversible so that polymerization can resume after hydrolysis of the misincorporated nucleotide. The relative orientation of the polymerase and exonuclease domains in B-family DNA polymerases is completely different from that in the A-family

enzymes; yet both types of enzymes evolved a pathway of facile shuttling of the primer terminus between the two domains.

The overall structure of the N-terminal domain is also largely conserved between various B-class DNA polymerases. It forms a three-lobed structure, with one lobe showing similarity with single-stranded DNA-binding motifs and a second lobe showing similarity with ribonucleic acid (RNA)-recognition motifs. Given that all crystal structures of polymerase–DNA complexes show the single-stranded template DNA extruding toward a cleft between the N-terminal domain and the exonuclease domain, a likely function of the N-terminal domain is to bind the downstream single-stranded template DNA. In addition, Pol δ is involved in several pathways that require gap-filling reactions including those that occur during Okazaki fragment maturation on the lagging strand of the replication fork. Therefore, the N-terminal domain may recognize the downstream 5'-single-/double-stranded DNA junction during gap filling.

In addition to these three conserved domains shared with all B-family DNA polymerases, the cellular B-family enzymes uniquely contain a highly conserved C-terminal domain. This domain shows a typical structural arrangement of conserved cysteine residues that chelate divalent metals. In the case of Pol α , two Zn ions are found at these sites, and it is these motifs that mediate interactions with the other subunits of the complex. In addition to the structural functions ascribed to this C-terminal domain, it may also play a specialized function in mediating damage-induced mutagenesis in the cell as mutations in the domain are specifically defective for this process.

Associated Subunits

The second subunit of Pol δ shows considerable structural homology with the second subunits of Pol α and Pol ϵ . Given the high conservation of the metal-binding domains of the C-termini of the catalytic subunits, it is likely that subunit–subunit interactions between each of the three catalytic subunits with their respective second subunits are also conserved. The proposed subunit–subunit interface between yeast Pol3 and Pol31 in Figure 1(b) is based on the crystal structure of the homologous subunit interactions between the catalytic and second subunit of Pol α . A possible function for an OB-fold domain (oligonucleotide/oligosaccharide binding) in Pol31, beyond its involvement in subunit interactions, remains to be established. OB-fold domains are often active in binding single-stranded DNA.

The third subunit of Pol δ consists of a ~ 15 kDa N-terminal domain that mediates interactions with the second subunit, followed by a largely unstructured domain of 20–45 kDa, and a proliferating cell nuclear antigen (PCNA)-binding domain at the extreme C-terminus of the subunit. In addition, interactions with Pol α and with Rev1, a subunit of the cellular

mutagenesis complex, have been identified. The presence of the middle domain is responsible for the highly elongated structure of this subunit, and consequently of the entire Pol δ complex. *Saccharomyces cerevisiae* Pol32 is dispensable for growth, but the deletion shows defects in DNA replication, mutagenesis, and in break-induced DNA replication. By contrast, the *S. pombe* *Cdc27* gene is essential.

A small fourth subunit of Pol δ has been identified in human and *S. pombe*, but appears to be lacking from *S. cerevisiae* Pol δ . This subunit enhances the stability of the complex. It may also play a regulatory role during damage response in the cell as this subunit is specifically degraded after DNA damage.

PCNA as Processivity Factor

Pol δ has a very low processivity of DNA synthesis, which would make it an unsuitable enzyme for replicating long templates with high efficiency. However, its interaction with PCNA transforms Pol δ into a highly processive enzyme, capable of replicating thousands of nucleotides without dissociating from the DNA. PCNA is a donut-like homotrimer that encircles dsDNA and binds proteins, thereby locking them onto the DNA. In addition to Pol δ , almost a hundred other PCNA-interacting proteins have been identified that function in DNA metabolism and cell-cycle control.

Table 1 Subunit structure of Pol δ

Genes and subunit sizes			Function
<i>S. cerevisiae</i>	<i>S. pombe</i>	Human	
<i>POL3</i> 125	<i>Pol3</i> 124	POLD1 124	Polymerase, 3'-exonuclease
<i>POL31</i> 55	<i>Cdc1</i> 51	POLD2 51	Required for PCNA-dependent replication
<i>POL32</i> 40	<i>Cdc27</i> 42	POLD3 66	PCNA binding
-	<i>Cdm1</i> 19	POLD4 12	Complex stability

Gene designations and subunit sizes in kDa are given.

The PCNA-binding domain at the C-terminus of the third subunit of Pol δ is responsible for DNA-independent interactions with PCNA. When both PCNA and Pol δ are assembled onto DNA, additional PCNA-interaction domain(s) become active in promoting processivity. The precise domain(s) in Pol δ responsible for these DNA-dependent interactions with PCNA still remain to be mapped. However, PCNA-dependent processive DNA replication requires at a minimum both the catalytic and second subunit of Pol δ .

Functions of Pol δ

The two catalytic functions of Pol δ , that is, polymerization and 3'-exonuclease, support high-fidelity DNA replication, a necessary function for genome maintenance. In addition, these two catalytic functions have been adapted for specialized functions of Pol δ , in particular those involving gap-filling reactions. During gap filling, when the downstream 5' ds/ss junction is reached, Pol δ can invade the double-stranded region and, thus, carry out strand-displacement synthesis. Remarkably, however, strand-displacement synthesis is limited to only a few nucleotides producing a very short 5'-flap that, depending of the pathway involved, is cleaved by an appropriate 5'-exonuclease. In the absence of this processing by the 5'-exonuclease, Pol δ switches the primer terminus to its 3'-exonuclease domain that degrades the extended terminus back to the nick position. The recurring process of extension and degradation, called idling, allows Pol δ to dynamically maintain the primer terminus either at the nick position, to promote ligation of the nick, or at a 5' flap position, for degradation by a 5'-exonuclease (Figure 2(a)). Idling prevents the generation of long flaps that can be a source for genomic instability.

DNA Replication

Recent studies have established that leading-strand DNA replication is carried out by Pol ϵ , while Pol δ is the lagging-strand

Figure 1 Structural components of Pol δ . All structures were rendered using Chimera, from coordinates deposited in the PDB database. (a) The *S. cerevisiae* Pol3 polypeptide, aa 95–985, in a complex with DNA (3IAY). The N-terminal, exonuclease and polymerase domains are indicated. The C-terminal domain of Pol3 is missing from this structure. (b) The C-terminal domain (3FLO) of *S. cerevisiae* Pol 1 (catalytic subunit of Pol α), which is highly homologous to that of Pol3, is docked onto the structure (3EOJ) of the human heterodimeric complex of p50 with p66 (N-terminal domain). The proposed connectivity between the N-terminal and C-terminal domains of Pol3 is indicated with a double gray arrow.

Figure 2 Activities and pathways of Pol δ . (a) Idling is the result of recurring cycles of polymerization and exonuclease activity. (b) Pathway involvement for Pol δ . See text for details. TLS, translesion synthesis.

DNA replicase. However, in the case of dysfunction of the leading strand replicase Pol ϵ , Pol δ can, in addition, perform leading-strand DNA replication. The ability of Pol δ to function on both strands may be important in some DNA damage-response pathways that operate at damaged or unusual DNA replication forks. Each Okazaki fragment on the lagging strand is initiated by the primase activity of Pol α -Primase. After a switch to Pol δ , the enzyme can correct replication errors that were made by Pol α during initiation. Pol δ elongates Okazaki fragments, which are ~150 nt in length, and also matures these fragments. The predominant pathway for maturation proceeds in cooperation with the 5'-exonuclease FEN1 and DNA ligase I. It is during maturation that the strand-displacement activity of Pol δ becomes important. By carrying out strand displacement synthesis, Pol δ dynamically generates the substrate for the FEN1 5'-flap exonuclease ensuring degradation of the RNA primer (Figure 2(b)). Once the RNA is degraded, DNA ligase I can seal the nick. All of these reactions are coordinated by interactions of each of these factors with PCNA.

When replication forks stall because of the presence of template DNA damage, several mechanisms are available to deal with this damage. One of these mechanisms is to

switch to a mutagenic form of DNA replication that involves low-fidelity DNA polymerases that replicate across the damaged template, a process called translesion synthesis (TLS). The activity of the low-fidelity TLS Pol ζ forms the basis for damage-induced mutagenesis in eukaryotic cells. Mutagenesis is a highly controlled process that involves the participation of several other factors. Genetic studies have shown that Pol δ is one of the factors essential for damage-induced mutagenesis. This is rather unexpected because Pol δ is a high-fidelity enzyme that would be very inefficient in TLS. Possibly, Pol δ has a role in organizing the mutagenic complex during TLS.

DNA Recombination

The repair of double-stranded breaks in the cell by homologous recombination is the most accurate repair mechanism as it uses the information on the homologous chromosome to repair the information lost at the break site. Homologous recombination is initiated by strand-specific resection from the double-stranded break in order to generate long 3'-single-stranded tails. These 3'-tails invade the intact homologous chromosome using standard leading to the formation of a D-loop. DNA synthesis using the 3'-terminated strand of the D-loop as a primer is an essential step in homologous DNA recombination as it restores the information lost at the initial break site. The strand-displacement synthesis in this step is carried out by Pol δ and its interaction with PCNA is essential in the initiation of this process. Resolution of recombination intermediates restores the proper genetic identity of the broken chromosome.

Double-stranded breaks can also be generated by collapse of stalled replication forks or by gradual degradation of the telomeric ends of chromosomes. Such breaks have only one broken end and do not undergo classical recombination. Rather, after strand invasion, they establish a replication fork that proceeds to the end of the invaded homologous chromosome, hence break-induced replication (BIR). During the initial stages of BIR, replication is carried out by Pol δ . Remarkably, in the absence of the nonessential Pol32 subunit of Pol δ , BIR is largely defective. Only at later stages of BIR is a more standard replication fork generated that also contains Pol ϵ .

DNA Repair

Among the various DNA repair pathways, both base excision repair (BER) and nucleotide excision repair (NER) involve a DNA synthesis step. Two distinct pathways exist for removal of damaged nucleotides in BER. After 5'-incision of the damaged strand, repair can proceed either through a Pol β -dependent pathway or through a Pol δ -dependent pathway. The latter pathway is also called long-patch or PCNA-dependent BER. The damage is removed by PCNA-dependent strand-displacement synthesis by Pol δ coordinate with PCNA-promoted excision of the damaged strand by FEN1. This pathway is comparable to that of RNA degradation during Okazaki fragment maturation. In contrast to BER, it is less clear which DNA polymerases carry out the required synthetic step during NER. NER proceeds by excision of a ~30-nt section of

single-stranded DNA surrounding the DNA damage leaving a gapped DNA intermediate. Genetic studies in yeast have implicated both Pol δ and Pol ϵ as enzymes capable of carrying out gap-filling synthesis. However, there is evidence that in human cell, the low-fidelity Pol κ may also serve a role in gap filling.

Glossary

E, A, P, and F sites Physical locations in the intersubunit space of the ribosome that are occupied by aminoacyl-, peptidyl-tRNA, or free tRNA.

Elongation (of protein synthesis) The sequential steps that lead to the addition of one amino acid at a time to the growing polypeptide chain.

Elongation factor (EF) A nonribosomal protein that facilitates the process of elongation only. (note: eukaryotic elongation factors are designated eEF where the lower case 'e' signifies 'eukaryotic').

Initiation (of protein synthesis) The required steps that lead to the placement of the initiator transfer RNA (tRNA) in the P site of the ribosome, correctly base paired with the initiating AUG codon.

Protein synthesis The process of joining amino acids in a specific sequence through the α carbonyl and α amino groups via a peptide bond that is templated by an mRNA molecule.

Termination (of protein synthesis) The codon-directed (UAA, UAG, or UGA) process of cleavage (and therefore, release) of the polypeptide chain from the tRNA in the P site of the ribosome.

Introduction

Protein synthesis (i.e., translation) is a complex event catalyzed by over 20 factors in eukaryotes and regulated by many more. That said, the purpose of this article is to provide a basic understanding of the process of translation elongation, a central step in the protein's synthesis, leading to the sequential addition of amino acids to the polypeptide chain. Although the focus will be on eukaryotic systems, the factors involved and the general mechanism of protein synthesis elongation are essentially conserved in eukaryotes and prokaryotes (see Table 1). This is perhaps not surprising given the ease with which one can trace the evolution of the eukaryotic factors from their bacterial predecessors. At present, the most complete biochemical and structural data on the elongation cycle comes from bacterial systems and includes crystallographic structures of the 70S ribosome in complex with messenger RNA (mRNA) and transfer RNAs (tRNAs). Recently, X-ray structures of the 70S ribosome in complex with individual elongation factors and their various substrates and cofactors (in particular, EF1A-GDP, EF2-GDP, and EF1A-GDPNP-Phe-tRNA^{Phe}) have emerged. In addition, valuable structural information and many mechanistic insights have been obtained from the cryo-electron microscopy structures of ribosomes (from both prokaryotes and eukaryotes) in complex with initiation, elongation, termination, and recycling factors. The regulation of the elongation cycle has been studied in the eukaryotic system with several posttranslational modifications of the elongation factors that appear to influence the rate of peptide synthesis. Much of the kinetic information regarding the elongation cycle has been obtained from the prokaryotic system. These data have most recently come from sophisticated experiments employing pre-steady state kinetic measurements and single-molecule fluorescence resonance energy transfer (FRET) analysis utilizing labeled components of the reaction.

The Traditional Eukaryotic Elongation Cycle: The A and P sites

The elongation cycle is defined as a process leading to the sequential addition of amino acids to the polypeptide chain. It is catalyzed by a set of extremely conserved elongation factors, whose function is depicted in Table 1. After initiation, the 80S ribosome is bound to mRNA (or AUG codon) correctly base paired with the initiator tRNA (Met-tRNA_i) in the peptidyl or P site of the ribosome (see Figure 1). This placement of the initiator tRNA in the P site sets the reading frame for all subsequent aminoacyl-tRNAs (aa-tRNAs). The next event is the binding of the ternary complex (eEF1A-GTP-aa-tRNA) to the aminoacyl site (A site) (see Figure 1). This binding is directed by the interaction of the anticodon of the tRNA and the three nucleotides of mRNA in the A site. The specificity is such that perfect Watson-Crick base pairs are observed for the first two nucleotides in the codon (i.e., only A-U or G-C base pairs), but altered base pairing is possible at the third position (as originally proposed by Crick). The Genetic Code dictates which aa-tRNA will bind to the A site in response to the 61 possible triplet codons that specify an amino acid (note: three codons of the possible 64 are stop codons: UAA, UAG, and UGA). This process, called decoding, is regulated by the ribosomal RNA of the 40S subunit. If a correct codon-anticodon base pair forms between the mRNA and the incoming aa-tRNA, a conformational change occurs which triggers the hydrolysis of guanosine triphosphate (GTP) leading to the release of eEF1A-GDP from the ribosome.

Decoding is followed by peptide bond formation. The synthesis of the peptide bond is catalyzed by the peptidyl transferase center in the large ribosomal subunit (60S). *In vivo*, this step appears to occur instantaneously and is likely the most rapid step in the entire process of elongation. Decoding and peptide bond formation (as should be noted in Figure 1) lead to the movement of the upper halves of the two tRNAs such

that the tRNA originally in the P site is now half in the E site (aminoacyl end) of the 60S subunit, while the lower half of the tRNA remains in the P site (the anticodon end) of the 40S subunit. The partial translocation of the tRNA molecule results in a hybrid, P/E-site tRNA. In a similar manner, the tRNA originally in the A site now resides in an A/P-hybrid state. The hybrid tRNA states are formed in the absence of eEF2 and are authentic intermediates in the elongation process.

The final step in the elongation cycle is translocation. Translocation is driven by the binding of eEF2-GTP to the A site of the ribosome. Hydrolysis of the GTP in the eEF2-GTP complex, which is stimulated by the ribosomal stalk, triggers the

movement of the peptidyl-tRNA in the A/P-hybrid site into the canonical, P/P site. By moving the anticodon of the peptidyl-tRNA fully into the P site (P/P), the mRNA is moved along the ribosome precisely by three nucleotides (or one codon). In this manner, the ribosome maintains the reading frame of the mRNA. It should be noted that translocation is accompanied by a rotational movement (ratchet) of the ribosomal subunits relative to each another. These conformational changes involve a ratchet-like rotation of the 40S subunit with respect to the 60S subunit. The combination of eEF2 binding, GTP hydrolysis, and ratcheting of the ribosomal subunits results in two distinct states: the posttranslocational state, where the ribosome has a peptidyl-tRNA in the P site and a vacant A site ready to decode an incoming aa-tRNA and the pretranslocational state, where the ribosome has a deacylated tRNA in the P site and a peptidyl-tRNA in the A site.

After each round of elongation, the entire process is repeated for each amino acid encoded by the mRNA transcript until the mRNA reaches a STOP codon. During the elongation cycle, and as noted above, eEF1A is released as an eEF1A-GDP complex. The binding affinity of eEF1A for GDP is about 0.1 μM . Thus, in biological terms, this is a rather stable complex. To enhance the conversion of eEF1A-GDP into the biologically active eEF1A-GTP form, the eEF1A-GDP complex binds to eEF1B (a nucleotide exchange factor). eEF1B is composed of two subunits, eEF1B α and eEF1B γ , in yeast and three

Table 1 Eukaryotic and prokaryotic components of the elongation cycle

Prokaryotes	Eukaryotes	Function
30S, 50S subunits	40S, 60S subunits	Peptide bond formation
EF1A	eEF1A	Binding of aa-tRNA to ribosomes
EF1B	eEF1B	Nucleotide exchange factor
EF2	eEF2	Translocation
tRNA	tRNA	Carrier of the activated amino acid (as aa-tRNA, recognition of the codon in the A site)

Figure 1 The traditional elongation cycle: the A and P sites. Shown above is the elongation cycle with the traditional A and P sites (aminoacyl and peptidyl sites, respectively). Following initiation, subsequent steps in the elongation cycle ensue with aminoacyl-tRNA binding, peptide bond formation, and then translocation. This process continues until a stop codon (UAA, UAG, or UGA) appears in the A site at which point termination occurs.

subunits, eEF1B α , eEF1B γ , and eEF1B β , in mammals. The catalytic domain necessary for nucleotide exchange is located on the eEF1B α subunit. Interaction of eEF1A-GDP with eEF1B leads to the release of GDP and the formation of an eEF1A-1B complex. Subsequent binding of GTP yields eEF1A-GTP + eEF1B. By contrast, eEF2 does not require an exchange factor as it has a much poorer affinity for guanosine diphosphate (GDP) and thus GDP is rapidly released from eEF2 following GTP hydrolysis and subsequent dissociation from the ribosome.

There are a few points regarding the thermodynamics and kinetics of the elongation cycle. First, the energy cost would appear to be 2 high-energy phosphates per cycle; however, the actual value is 4 when one considers that 2 high-energy phosphates were required for the attachment of the amino acid to the tRNA (i.e., charging) that was then placed in the A site. Second, on careful examination, it becomes apparent that the synthesis of the peptide/protein is from the amino terminus to the carboxy terminus of the growing polypeptide, while the mRNA codons are read in a 5'-3' direction. It should also be noted that movement of the ribosome on the mRNA is not a uniform process. Translation rates of individual codons might differ substantially (5- to 25-fold) and mainly depend on the concentration(s) (which appear to be different) of cognate

aa-tRNAs surrounding the ribosome during translation. It is assumed that aa-tRNAs (in complex with eEF1A and GTP) randomly encounter the A site and become temporally trapped. Trapped species are then tested for proper pairing with the corresponding codon in the A site (i.e., decoded). If the pairing is correct, the transpeptidation reaction becomes irreversible; if not, the ternary complex (eEF1A-GTP-aa-tRNA) is then rejected and another complex is processed in turn.

Elongation Cycle Chemistry

Shown in **Figure 2** is the chemistry that occurs with peptide bond formation. Although most of the details described below were elaborated for the prokaryotic system, it is believed that the general mechanism is the same for all the kingdoms of life. The central event in peptide bond formation is the nucleophilic attack of the amino group of the second amino acid (R2) on the ester carbon of the initiating amino acid methionine (R1), or the amino acid of the peptidyl-tRNA in the P site, in case the ribosome already moved down the mRNA by one or more codons (**Figure 2(a)**). The ribosome accelerates this reaction approximately $\sim 10^5$ -fold. It was originally thought that

Figure 2 Elongation cycle chemistry. Shown above is the chemistry thought to occur during the process of elongation. Nucleophilic attack by the amino group in the A site on the carbonyl bond of the amino acid in the P site leads to an amino-tetrahedral intermediate (b). The primary role of the ribosome in peptide bond formation is to facilitate the forward reaction by the use of proton-shuttling mechanism. The chemistry is completed by subsequent cleavage of the ester bond to the tRNA in the P site (c). The cycle is further followed by translocation (d). Binding of a new aminoacyl-tRNA (as an eEF1A-GTP-aminoacyl-tRNA complex) starts the beginning of a new cycle (a).

the peptide bond formation on the ribosome involves an acid/base mechanism of catalysis; however, recent experiments clearly indicate that this is not the case and there is no general acid/base catalysis involving any of the ribosomal counterparts. Instead, a proton-shuttling mechanism was proposed, whereby the 2' OH of A76 of the peptidyl-tRNA simultaneously accepts a proton from the α -amino group and donates one to the 3' O⁻ leaving group (Figure 2(b)). An extensive network of hydrogen bonds has therefore been proposed to allow proper positioning of the substrates for reaction. The bond between the 3' oxygen of the terminal adenosine in the tRNA in the P site and the methionine is then cleaved, completing the transfer of the methionine to the amino group of the second amino acid with formation of the peptide bond (Figure 2(c)). Finally, with eEF2 catalyzed translocation, the peptidyl-tRNA is moved completely into the P site (Figure 2). In the overall thermodynamics of the reaction, the resulting peptide bond is of low energy while the original aminoacyl linkage is high energy (equivalent to that in adenosine triphosphate (ATP)) and, thus, the net ΔG for peptide bond formation is quite negative (i.e., extensive heat is released with the completion of the reaction). Although most primary amines would be expected to have a pK_a of about 9–10, that of the α amino groups is about 7.5 due to the inductive effects of the ester linkage of the amino acid to the tRNA (in a similar manner, the pK_a of the amino group at the amino terminus of the peptide/protein is also about 7.5). Thus, at physiologic pH values, the nucleophilic amino group is positively charged only about 50% of the time. A reactive N3 amine of the conserved nucleotide A2451 in ribosomal RNA, which is in close proximity to the CCA ends of aminoacyl and peptidyl-tRNAs, was originally suggested to be indispensable for the general acid/base mechanism of catalysis. However, as indicated above, recent evidence proved its dispensability. Thus, the exact details of the catalytic mechanism are not fully known and the ribosome is suggested to work mainly by properly orienting the substrates and providing an environment that reduces the free energy of formation of the polar transition state.

Molecular Mimicry

High-resolution crystal structures of prokaryotic ribosomes as well as cryo-EM structures of eukaryotic ribosomes have contributed a great deal to our understanding of the mechanism of protein synthesis. The structure of individual elongation factors, alone and in complex with the ribosome, has also been solved providing further insights into the molecular basis of the protein synthesis. The crystal structures of eukaryotic eEF1A and eEF2 revealed high similarity to their bacterial homologs. Comparison of the structures to each other and to the bacterial proteins indicated that to a first approximation they have a similar size, shape, and electronic distribution. While this might have been expected for the GTP-binding domain of EF2, EF2 has a unique protein finger that appears to be the mimic of the anticodon stem and loop of a tRNA by overall size and charge (rich in aspartic and glutamic acid residues); this initially was not expected for the other factor(s). However, subsequently it has been found that other factors

(including termination/release factors) that are expected to encounter and bind the ribosome at the A site have very similar shapes overall approaching the shape of tRNA. The ability of a protein to take on the apparent characteristics of RNA is known as 'molecular mimicry'. Although not discussed here, it has been further proposed that all other factors that bind to this region of the ribosome are also molecular mimics and will yield structures similar to that (at least in some parts) of the L-shaped tRNA molecule.

Influence of Other Sites

In the discussion above, reference was made to an (exit) E site (see also Figure 3). This site, to the 5' side of the P site, has been visualized by X-ray crystallography (in prokaryotes), cryo-electron microscopy (in both pro- and eukaryotes) and inferred by nuclease footprinting. The most important effect of the E site is that it appears to increase the stringency for the correct matching of the codon and anticodon in the A site of the ribosome. It should be noted that for the original binding of the first aa-tRNA, Met-tRNA_i, the E site was unoccupied. One might anticipate that this would allow for less stringent recognition of the initiating AUG codon; however, this strict recognition appears to result from the unique set of factors associated with the initiation process. A second proposed site is the F site or entry site which is just 3' of the A site. This may be an initial test-binding site (check of codon/anticodon match) such that correctly matching complexes would be pulled into the A site while incorrectly matching complexes would dissociate. The advantage of an F site would be that it would be more accessible to ternary complexes of eEF1A-GTP-aa-tRNA as both the A site and the P site appear to be partially occluded at the interface of the large and small ribosomal subunits. However, the biochemical evidence supporting the existence of the F site is weak compared to that for the E site.

Assuming that all four of the ribosomal sites are functional and exist, they can be characterized by positions of the tRNAs on either the large or small ribosomal subunits. Thus, following initiation, the Met-tRNA_i may be described as being in the P/P position (both the aminoacyl end and the anticodon end of the tRNA correspond to the P site; see Figure 3(a) or 3(c)). In the next step, the initial binding of the aa-tRNA is to the F/A site where the anticodon is in the A site, but the aminoacyl end is in the F site and this end of the aa-tRNA is still bound to eEF1A-GTP (Figure 3(d)). With correct codon/anticodon recognition, GTP is hydrolyzed and eEF1A-GDP is released from the ribosome concomitant with the movement of the aminoacyl end of the tRNA into the A site (now in the A/A configuration, Figure 3(a)). At the same time, any tRNA in the E site (as would be true for most elongation steps) would be released from the ribosome. Subsequent reactions would cyclically yield the other states of the ribosome (P/P A/A, A/P, P/E, and then E/E P/P). Additional intermediate states have also been suggested, but are not discussed here for simplicity and because the states noted above have been suggested to represent the major configurations. 'Snapshots' of the translocation cycle as determined by cryo-electron microscopy (some for the yeast *Saccharomyces cerevisiae* 80S ribosome, and others for *Escherichia coli* 70S complexes) are shown in Figure 4.

Figure 3 Elongation cycle: influence of other sites. Illustrated in this figure are the four proposed tRNA-binding sites in the eukaryotic ribosome. The A and P sites are the traditional tRNA binding sites on the ribosome (see Figure 1). The E site (exit site) and the F site (entry site) are also shown. Note that a portion of each site is located on the small (40S) and the large (60S) ribosomal subunit. In the designation for the tRNA molecules, the upper letter indicates position on the 60S subunit and the lower letter indicates position on the 40S subunit.

The Other Elongation Factors, eEF3, eEFSec

Protein synthesis in yeast and fungi requires an additional unique translation elongation factor, eEF3. This protein, which is an ATPase, contains two nucleotide-binding sites, and appears to be required for the nucleotide-dependent release of the non-acylated tRNA from the ribosomal E site. As this protein is an essential gene product in yeast, it is surprising that an equivalent activity has not been identified in higher eukaryotes. However, it has been noted *in vitro* that only elongation reactions using yeast ribosomes demonstrate the eEF3 requirement and thus, this requirement for eEF3 would appear to reflect unusual properties of the yeast and fungal ribosome compared to other eukaryotic ribosomes. Recently, the crystal structure of the yeast *S. cerevisiae* eEF3 was solved and the position of the factor on the surface of the 80S ribosome was mapped using cryo-EM. In contrast to other elongation factors, eEF3 was found to occupy an unusual place on the 80S ribosome surface in close proximity to the E site. Although all other elongation factors bind 80S ribosome at the A site, this unusual location of eEF3 coincides well with its function.

A 21st amino acid (i.e., Selenocysteine (Sec)) is incorporated at certain UGA codons in mRNAs and requires a specific translation elongation factor (eEFSec), a functional homolog of eEF1A, capable of recognizing the unique Sec-tRNA^{Sec} (anticodon UCA)

and delivering the Sec-tRNA^{Sec} to the ribosome in a ternary complex with GTP. In eukaryotes, the incorporation of selenocysteine also requires a SECIS-binding protein 2 (SBP2) capable of recognizing both the sec insertion sequence (SECIS) element in the 3'-untranslated region of mRNAs and eEFSec. In prokaryotes, the recognition of SECIS element and Sec-tRNA^{Sec} delivery is performed solely by elongation factor SelB. The requirement for an additional protein SBP2 in eukaryotes for incorporation of the Sec-tRNA^{Sec} has been attributed to the difference in the structural organization of the eukaryotic and prokaryotic proteins, respectively. Prokaryotic SelB is a multidomain protein consisting of an N-terminal RNA-binding domain and a C-terminal eEF1A-like domain. Eukaryotic SelB contains only the eEF1A-like domain and lacks the RNA-binding domain and, therefore, relies on the additional SelB-binding protein, SBP2, for its interaction with mRNA. The crystal structure of the archaeal SelB has been recently determined, confirming its similarity to other elongation factors in the family.

Regulation of the Elongation Cycle

The major regulation of gene expression at the translational level occurs through the covalent modification of translation initiation factors or regulatory proteins that bind to the

Figure 4 Structural models of the translocation cycle. The structure of the yeast 80S ribosome, as determined by cryo-electron microscopy, is shown with the 60S in blue and the 40S in yellow. (a) The ribosome contains A and P site tRNAs shown in magenta and green, respectively. (b) After peptide-bond formation, the upper half of the tRNAs migrate to the next binding site on the 60S subunit, while the lower halves remain stationary on the 40S subunit. This results in hybrid-state A/P- and P/E-site tRNAs. (c) eEF2 binds the ribosome in its GTP-bound conformation. (d) Binding of eEF2 to the ribosome catalyzes GTP hydrolysis, which assists in translocating the lower portions of the tRNA molecule to the next site on the 40S subunit. (e) Dissociation of eEF2 in its GDP-bound conformation leaves the ribosome with P and E site tRNAs and a vacant A site. (f) eEF1A bound to GTP delivers the next aa-tRNA to the A site, which is decoded by the ribosome. GTP-hydrolysis, again induced by binding to the ribosome, releases eEF1A from aa-tRNA and the ribosome. Occupation of the newest tRNA in the A site completes the cycle.

initiation factors. However, there is ample evidence that regulation of translation also occurs at the level of elongation although the degree of regulation (the fold change in the elongation rate) is not as great as seen with regulation of the initiation step. While eEF1A, eEF1B, and eEF2 are all phosphorylated under different conditions, eEF1A and eEF2 also contain unique posttranslational modifications. eEF1A contains methylated lysines (mono-, di-, or trimethyl lysine) and glycerylphosphorylethanolamine. eEF2 contains a hypermodified histidine residue (histidine #714 in mammalian eEF2's) that is found in all eukaryotic eEF2's and is called diphthamide. The diphthamide residue is a known inactivation site for ADP-ribosylation catalyzed by either *Diphtheria* or *Pseudomonas* A toxins with nicotinamide adenine dinucleotide (NAD) serving as the donor of the adenosine diphosphate (ADP) group. There is tentative evidence that this modification may be part of the normal cellular regulation of eEF2 activity as well.

The best-studied regulation of any of the elongation factors is via phosphorylation. In general, phosphorylation of eEF1A and eEF1B correlates well with increases in the rate of elongation noted *in vivo* with either insulin or phorbol ester treatment. Additionally, most phosphorylations of translation factors are associated with an increased rate of protein synthesis. By contrast, the phosphorylation of eEF2 leads to its inactivation. Under most circumstances, changes in the elongation

rate due to changes in covalent modifications of eEF1A, eEF1B, or eEF2 are associated with a coordinate change in the rate of initiation of protein biosynthesis.

The Ribosome and the Nobel Prize

The 2009 Nobel prize in chemistry was awarded to Drs. Venkatraman Ramakrishnan, Thomas A Steitz, and Ada E Yonath for the 'studies of the structure and function of the ribosome'. The work is undoubtedly unique, as for the first time the structure of such large, highly complex, and asymmetrical particles, consisting of both proteins and RNA has been solved by X-ray crystallographic analysis. The Nobel-winning crystal structures of the prokaryotic ribosomes clarified many aspects of the ribosome work and provided answers to many long-standing questions. In particular, analysis of codon-anticodon interactions within the ribosome provided new insights into codon reading and showed that the ribosome is a thermodynamic machine strengthening codon/anticodon interactions and thus providing stabilization above the ΔG of simple base pairing. Tantalizing efforts to solve the crystal structure of eukaryotic ribosomes are bringing first results and will undoubtedly provide additional insights into the mechanism of eukaryotic protein synthesis and its regulation.

Glossary

Brown adipocyte Adipose cell type with a large number of mitochondria whose primary function is to conduct fat oxidation that is uncoupled from adenosine triphosphate synthesis via mitochondrial protein, uncoupling protein 1 (UCP1).

Energy homeostasis Physiological state when energy intake and energy utilization are matched to produce stable body weight.

Leptin A 16-kDa hormone secreted by adipose tissue that regulates the balance between food intake and energy utilization.

Obesity Excessive fat storage resulting from chronic positive energy balance.

Sympathomimetic Endogenous or synthetic agonist of adrenoceptors.

Transdifferentiation A programmatic change in gene expression in white adipocytes which transforms their morphology and functionality from fat storage to fat oxidation.

Uncoupling protein 1 Specialized mitochondrial protein that short-circuits the proton gradient across the mitochondrial matrix, uncouples oxidative phosphorylation, and transforms electrochemical energy into heat energy.

Leptin is a 16-kDa peptide hormone released from adipose tissue that regulates the balance between energy intake and energy utilization by binding to hypothalamic receptors and modulating appetite control centers in the brain. Occupancy of central leptin receptors also increases activity of the sympathetic nervous system, which stimulates energy expenditure in peripheral target tissues through a process called 'adaptive thermogenesis'. Through coordinated regulation of these two systems, leptin functions to match rates of energy expenditure with energy intake. Leptin also functions to preserve energy reserves during starvation by lowering body temperature, basal metabolic rate, and limiting hypothalamic support for reproductive function. As such, leptin is a peripheral signal that acts centrally to integrate a complex array of behavioral and metabolic systems that function to maintain energy homeostasis when food supplies are adequate and ensure survival when they are not.

Historical Perspective of Leptin Discovery

The search for the primary genetic defect giving rise to the obese/diabetic syndrome of *ob/ob* mice (Figure 1) was guided by the early work of Douglas Coleman, who postulated that *ob/ob* mice were missing a circulating satiety signal. To test this hypothesis, he surgically joined *ob/ob* mice with lean littermates, *ob/ob* mice with *db/db* (diabetes) mice, and lean mice with *db/db* mice so that the parabiotic pairs shared blood supplies. The *db/db* mice were included in his experiments because they also developed morbid obesity after weaning but differed from *ob/ob* mice in that the *db/db* mutation resides on a different chromosome. This landmark experiment showed that the obesity syndrome of *ob/ob* mice, but not *db/db* mice, was corrected by a circulating factor from lean mice. The obesity syndrome of *ob/ob* mice was also reversed by parabiotic

pairing with *db/db* mice, but, in this case, the *ob/ob* mouse eventually died from starvation. The results indicate that *ob/ob* mice were missing a satiety factor but retained the ability to respond to the missing factor. By contrast, *db/db* mice were unresponsive to the satiety factor, but apparently produced it in abundant quantities. Nearly 30 years later, the missing factor (and receptor) inferred from the work of Coleman was identified by Jeffrey Friedman at Rockefeller University with the cloning of the *ob* gene (now officially called '*lep*'), in late 1994. The cloning of the *ob* receptor gene (now officially called '*lepr*') by Louis Tartaglia followed soon thereafter. The product of the *ob* gene was named leptin, from the Greek leptos, meaning thin.

The Obesity Syndrome Produced by Leptin Deficiency in *ob/ob* Mice

The cloning of the *ob* gene identified leptin as a lipostat, which regulates the balance between energy intake and utilization to maintain body weight homeostasis. Adipocytes of *ob/ob* mice do not produce leptin, and its absence produces a complex metabolic syndrome characterized by hyperphagia, morbid obesity, and diabetes. Hypertrophy of adipose tissue is noted prior to the hyperphagia that develops after weaning in *ob/ob* mice, and obesity occurs even when *ob/ob* mice are pair-fed with lean littermates. Thus, their thriftiness is a significant component of their propensity to become obese. Treatment of *ob/ob* mice with exogenous leptin corrects their obesity, and part of the weight loss can be accounted for by reductions in food intake. However, even after controlling for differences in food intake between saline and leptin-injected *ob/ob* mice, leptin-injected mice still lose more weight. These results illustrate that an important component of leptin's physiological actions is to regulate the metabolic efficiency of fuel oxidation.

Central Mechanisms of Leptin Action

Leptin is a key component of a homeostatic system that functions to match energy intake with energy expenditure. The adipocyte-derived hormone produces these effects through coordinated but reciprocal regulation of food intake and energy expenditure in peripheral tissues, and both sides of this balance are regulated via the neuroendocrine axis and autonomic nervous system. Neurons expressing the leptin receptor are found in many areas of the brain, and the current consensus is that integration of all signals from these neurons is necessary for the full effect of leptin on energy homeostasis (Figure 2).

The *ob* receptor is encoded by the *lepr* gene, which is translated into six distinguishable receptor isoforms (LepRa–f) by alternative splicing, but only LepRb – also referred to as the ‘long LepRb’ isoform – consists of a long intracellular signaling domain. LepRb is the main receptor that mediates leptin action, demonstrated in *db/db* mice. *Db/db* mice lack the long intracellular LepRb domain and retain normal expression of other LepR isoforms, which is sufficient to recapitulate the phenotype of leptin deficient *ob/ob* mice. LepRb is expressed

throughout the central nervous system and even though there is evidence for the existence of peripheral leptin targets, central leptin action adequately imitates phenotypes observed in *ob/ob* and *db/db* mice.

Leptin action in the hypothalamic arcuate nucleus (ARC) has been particularly well studied with the focus on two distinct neuronal populations: one population co-expressing the anorexigenic neuropeptides pro-opiomelanocortin (POMC) and cocaine and amphetamine-regulated transcript (CART) and another population co-expressing the orexigenic neuropeptides agouti-related peptide (AgRP) and neuropeptide Y (NPY). Leptin induces the transcription of CART and POMC messenger RNA (mRNA) and stimulates POMC/CART neuronal activity to increase the release of CART and the POMC cleavage product α -melanocyte stimulating hormone (α -MSH). By contrast, leptin decreases AgRP and NPY transcripts and inhibits NPY/AgRP neuronal activity to decrease their neuropeptide release. Thus, leptin differentially acts on these inversely acting neuronal populations.

Both neuronal populations have been well documented to project into the paraventricular hypothalamus – a major neuroendocrine output site – as well as to preganglionic neurons of the sympathetic nervous system, where the differential action of leptin on POMC/CART and NPY/AgRP neurons activates melanocortin and CART receptors to decreased food intake and increased sympathetic outflow. The resulting increase in sympathetic stimulation of liver, muscle, and adipose tissue promotes fat oxidation through targeted effects on futile energy cycles in the respective tissues. The effector systems in target tissues involve signaling through both β -adrenoceptors and adenosine monophosphate (AMP) kinase to produce an integrated increase in fuel oxidation. Thus, it is through reciprocal regulation of several leptin-responsive neurons that leptin produces its full effect on energy homeostasis (see Figure 2).

In addition to LepRb neurons in the ARC, a large network of LepRb-expressing neurons is found in several central sites. LepRb neurons are aggregated into populations that outline several hypothalamic nuclei as well as midbrain and brainstem structures (Figure 3) and support an overall role of leptin in

Figure 1 *ob/ob* mouse and lean littermate (+/?) 12 weeks after weaning.

Figure 2 Integrated model of leptin synthesis, secretion, and function. Leptin regulates its own expression and secretion from white adipose tissue and peripheral fatty acid oxidation through central modulation of sympathetic outflow to target tissues.

Figure 3 The schematic drawing of a mouse brain (a) shows the relative brain levels of fluorescent images depicted from coronal sections of a reporter mouse with green fluorescent protein expression in LepRb neurons. Examples of LepRb-expressing sites in the hypothalamus (b), midbrain (c), and brainstem (d) are shown to demonstrate the outlining of specific LepRb populations. LHA, lateral hypothalamic area; DMH, dorsomedial hypothalamus; 3V, 3rd ventricle; VMH, ventromedial hypothalamus; ARC, arcuate nucleus; PAG, periaqueductal gray; EW, edinger westphal nucleus; VTA, ventral tegmental area; IP, interpeduncular nucleus; AP, area postrema; NTS, nucleus of the solitary tract; cc, central canal.

neuroendocrine, autonomic, and limbic functions. Indeed, in addition to leptin's obvious role in the control of food intake and energy expenditure, other physiologic functions have been well documented, including reproduction, thyroid and immune function, glucose homeostasis, and growth.

However, the specific physiological function of leptin in these distinct LepRb populations outside the ARC is largely unknown. Even though the ARC is an important contributor of leptin action, recent studies using conditional deletion of LepRb in POMC and/or AgRP neurons showed a surprisingly moderate effect on body weight. Other central leptin targets in the hypothalamus (ventromedial hypothalamus, lateral hypothalamic area), midbrain (ventral tegmental area), and the brainstem (nucleus of the solitary tract) have been found to contribute to leptin action on body weight regulation. By contrast, LepRb expressing neurons in the hypothalamic pre-mammillary nucleus have been mainly associated with reproductive function. Further studies are under way to dissect the neuronal circuits and physiologic function of distinct LepRb populations.

Adipose Tissue as a Target of the Sympathetic Nervous System

Mitochondrial oxidation of fatty acids creates a proton electrochemical gradient that is used to drive the conversion of adenosine diphosphate (ADP) to adenosine triphosphate (ATP) via ATP synthase. Brown adipose tissue (BAT) mitochondria possess an alternative pathway that allows protons to re-enter the mitochondrial matrix without coupling to ATP synthesis, and this pathway is mediated by uncoupling protein 1 (UCP1). UCP1 transforms electrochemical energy into heat, enabling

small mammals to survive exposure to cold. The sympathetic nervous system and UCP1 are essential components of this thermogenic response system. Brown adipocytes are also unique in the sense that they are capable of simultaneously oxidizing glucose and fatty acids and conducting *de novo* lipogenesis. In liver and muscle, increased glycolytic flux increases formation of the substrate malonyl-coenzyme (malonyl-CoA) needed for the first committed step of *de novo* lipogenesis. In these tissues, the formation of malonyl-CoA potentially inhibits fatty acid oxidation by inhibiting carnitine palmitoyltransferase-1 β (CPT-1 β), which transports fatty acids into mitochondria for oxidation. These functions appear to be compartmentalized in brown adipocytes, so that increased glucose uptake and oxidation during cold exposure does not inhibit the high rate of fatty oxidation needed to support the thermogenic response to cold exposure. Maximal thermogenesis requires an adequate pool of long-chain fatty acids, which serve to stimulate their own uptake and oxidation within the mitochondria. However, increased cytosolic long-chain fatty acids inhibit fatty acid synthesis in liver and muscle, but this is not seen in BAT during cold exposure, where a high rate of *de novo* lipogenesis is required to support the high rate of mitochondrial fat oxidation. Although the mechanistic details are not yet firmly established, it is possible that high flux rates of inhibitory molecules (e.g., malonyl-CoA and long-chain acyl CoAs) mitigate their inhibitory effects on pathways that are normally mutually exclusive. The extent to which this paradoxical biochemistry occurs in physiological contexts other than cold exposure is also not known. However, it is clear that the simultaneous conduct of glucose oxidation, fat oxidation, and *de novo* lipogenesis constitutes an energetically inefficient substrate cycle that would waste energy, produce heat, and reduce the lipid content of tissues.

The conventional wisdom has been that UCP1 expression is restricted to brown adipocytes, but recent evidence has clearly established that sympathomimetics can induce ectopic expression of UCP1 in white adipose tissue (WAT) depots. The origin of the UCP1-expressing cells was originally a mystery, but evidence has emerged to support the concept that mature adipocytes are capable of significant functional plasticity, and readily transdifferentiate between cell types whose primary function is to store triglyceride (WAT) and multilocular, mitochondria-rich adipocytes capable of significant fat oxidation (BAT). It is clear that intense sympathetic nervous system (SNS) stimulation can also promote the differentiation of preadipocytes within white depot sites into brown adipocytes. The unexpected appearance of UCP1 in WAT was originally observed in mice, where cold exposure produced the emergence of islands of multilocular, mitochondria-rich brown adipocytes within WAT depots primarily composed of unilocular white adipocytes. Cold exposure produces these responses through increased sympathetic outflow to adipose tissue and induces the transcriptional program of differentiation or transdifferentiation within WAT depots through a norepinephrine, β -adrenoceptor, and cyclic adenosine monophosphate (cAMP)-dependent mechanism. SNS stimulation of adipose tissue is also subject to regulation by leptin, and in this case, modulation of SNS outflow has the effect of increasing thermogenic potential of both BAT and WAT.

The potential for emergence of brown adipocytes within WAT is depot-site specific and has a strong genetic component in both mice and humans. The significance of this process was demonstrated in elegant studies analyzing backcrosses of parental mouse strains with widely varying ability of WAT to form brown adipocytes. Using UCP1 as a BAT-specific indicator, Leslie Kozak showed that recombinant inbred strains from the crosses reduced fat deposition after adrenergic stimulation in direct proportion to their induction of UCP1 in convertible WAT depots. These findings indicated that the relative ability of a mouse strain to resist obesity is a function of the ability of WAT to increase UCP1 in response to adrenergic stimulation. Thus, an important component of leptin's ability to regulate energy utilization in peripheral tissues is conferred by its ability to induce UCP1 expression and enhance fat oxidation in adipose tissue. Some WAT depots do not respond to SNS stimulation with increases in UCP1 expression and fat oxidation. In this case, SNS stimulation activates lipolysis and mobilizes lipid for transport to more oxidatively active sites.

Regulation of Leptin Expression

Well before the discovery of leptin, George Bray proposed that most obesities known are low in sympathetic activity (MONA-LISA hypothesis). This hypothesis stemmed in part from the observation that *ob/ob* mice were cold intolerant, but after leptin and its receptor were cloned, it was noted that leptin mRNA was significantly upregulated in adipose tissue from both models. This indicated the absence of an efferent signal from the SNS in both models which was important in regulating leptin expression. Circulating leptin concentrations are the product of transcriptional regulation of the gene and release of

Figure 4 Ribonuclease protection assay of leptin mRNA in total RNA from EWAT of control (*Dbh*^{+/+}) and dopamine β -hydroxylase (*Dbh*^{-/-}) knockout mice injected with either saline, leptin, or the β 3-adrenergic receptor agonist, CL-316,243 for 3 days. The blot shows that the ability to synthesize catecholamines is required for leptin to downregulate its own expression in white adipose tissue. Reproduced from Commins SP, Marsh DJ, Thomas SA, et al. (1999) Norepinephrine is required for leptin effects on gene expression in brown and white adipose tissue. *Endocrinology* 140: 4772–4776, with permission from Copyright 1999, The Endocrine Society.

the expressed protein from adipocytes. Work in the author's laboratory established that leptin secretion from isolated adipocytes was inhibited by activation of β -adrenoceptors in parallel with the activation of cAMP-dependent protein kinase. As shown in Figure 4, leptin also regulates its own expression via the SNS, as mice lacking the gene which converts dopamine into norepinephrine (dopamine β -hydroxylase) were unable to downregulate leptin mRNA in WAT after treatment with exogenous leptin. Thus, the SNS is the efferent arm of a feedback system which negatively regulates leptin expression and release.

Leptin is positively regulated by insulin and glucocorticoids. Both hormones produce rapid increases in leptin secretion from adipose tissue in conjunction with a coordinated increase in transcription of the gene. These hormonal and neurotransmitter-dependent pathways represent acute regulatory systems that are superimposed onto a diurnal pattern of leptin secretion, which, in humans, produces lowest concentrations at night and highest during the day. Serum leptin levels are also strongly correlated to percentage body fat and body mass index, but the relationship is dichotomous between male and female patients. For instance, as body mass index increases, serum leptin levels increase threefold faster in females than males. Testosterone inhibits leptin expression and likely explains the gender difference in circulating leptin between males and females. Lastly, leptin is also responsive to nutrient-sensing systems that are regulated by meal composition. For example, increases in amino acids and insulin after a meal activate the mammalian target of rapamycin (mTOR) pathway which rapidly increases leptin synthesis and release. Considered together, leptin expression and release are regulated by a complex network of nutritional, hormonal, and autonomic inputs which are integrated to regulate transcription of the leptin gene and secretion of expressed protein into the bloodstream.

Leptin Resistance and Obesity

Diet-induced obesity in mice and humans is commonly associated with insensitivity to leptin, with high-circulating leptin levels and reduced anorexigenic leptin effects, and has been termed 'leptin resistance'. The development of leptin resistance may involve several levels and stages, including leptin transport mechanisms, cellular signaling mechanisms, as well as reorganization of axonal processes.

Leptin is too large a protein to cross the blood–brain barrier by perfusion, and a saturable, regulated transporter is needed for leptin access into the brain. Obese individuals show a reduced transport capacity of serum leptin into the cerebrospinal fluid, suggesting that the brain is exposed to lower leptin levels than available in the serum of obese individuals. This is further supported by the fact that leptin resistance in rodents can be improved (even though not entirely recovered) by central leptin application, thus bypassing the blood–brain barrier and the need for a transporter system and indicating that defective leptin transport depicts one component in the development of leptin resistance.

Leptin resistance is also manifested at the cellular level and a severe reduction in leptin-induced signal transducer and activator of transcription-3 (STAT3) phosphorylation. A deamplification of LepRb signaling can occur on several levels, for example, a decrease in LepRb availability or negative-feedback mechanisms via inhibitory molecules like suppressor of cytokine signaling-3 (SOCS-3) as well as protein tyrosin phosphatase PTP1B. SOCS-3 expression is induced by leptin signaling, and thus high circulating leptin levels may chronically increase SOCS-3 levels resulting in a decreased LepRb signal. PTP1B is also upregulated in response to leptin, resulting in decreased LepRb signaling; even though the specific molecular mechanisms are less well understood. Furthermore, even though leptin is able to induce the expression of SOCS-3 and PTP1B, they both are also regulated by other cytokines that are likely induced in obese subjects. Whole body deletion of either SOCS-3 or PTP1B, as well as neuron-specific deletion of SOCS-3 in POMC neurons, attenuates body weight gain on a high-fat diet and increased leptin sensitivity. Thus, inhibitory molecules such as SOCS-3 and PTP1B in specific neuronal populations like POMC neurons present a further level in the development of leptin resistance (Figure 5).

The concept that leptin induces its own resistance by inducing SOCS-3 and PTP1B has been discussed as a mechanism for increased weight gain on a high-fat diet. Indeed, chronic and central infusions of leptin cause leptin resistance over time. By contrast, low leptin levels have been commonly associated with increased leptin sensitivity, for example, fasted mice or leptin-deficient *ob/ob* mice are known to respond more sensitively to leptin treatment. The evolutionary importance of a system with major anorexigenic leptin effects when body weight is already low does not seem to be favorable. However, to evaluate the capability to survive energy-demanding periods, such as reproduction, a sensitive system to communicate body fat stores would be particularly important during famine and thus when fat stores are low.

Leptin resistance does not affect all physiological end points of leptin action. Whereas leptin resistance clearly blunts anorexigenic leptin effects, the sympathetic tone to the kidney

Figure 5 Schematic model of leptin signaling through LepRb, resulting in the activation of several signaling pathways as well as interaction with PTP1B and SOCS-3, which causes the deamplification of leptin signaling.

remains leptin sensitive in some obese mice, resulting in increased blood pressure in obese individuals with high circulating leptin levels. A selective leptin resistance has also been found in diet-induced obese mice and seasonal mammals with upregulated SOCS-3 and decreased leptin-dependent STAT3 phosphorylation specifically in the ARC, but not other hypothalamic sites. Neuronal processes of ARC LepRb neurons can access the circulation directly and respond more sensitively and faster to changes in circulating leptin as well as other obesity-induced cytokines compared to other hypothalamic sites. Therefore, ARC neurons would be more susceptible to increase SOCS-3 levels in response to high circulating leptin levels than other hypothalamic sites and could explain the appearance of ARC-specific leptin resistance. By contrast, pregnancy has been associated with leptin resistance confined to the ventromedial hypothalamus (VMH). Several LepRb neurons in the VMH also express estrogen receptors, so that interactions of the estrogen-signaling pathway with LepRb signaling might provoke VMH-specific leptin resistance during pregnancy, indicating that leptin resistance can be differentially modulated depending on the physiological context.

Leptin resistance could also occur at the level of translation of SNS input in peripheral tissues. In adipose tissue, activation of β -adrenoceptors initiates the transcriptional program of adaptive thermogenesis in a cAMP-dependent manner. Analysis of the promoter structure of many genes transactivated during this response shows that the nuclear receptor, peroxisome proliferator-activated receptor γ (PPAR γ), is an essential component of the transcriptional complex. Although the endogenous ligand for this receptor has yet to be identified, *in vitro* studies have shown that long-chain-polyunsaturated fatty acids and their metabolites can act as partial agonists. The relevance of PPAR γ to adaptive thermogenesis is apparent from work with obesity-prone strains of mice, where it is known that high-fat diets compromise the ability of sympathetic stimulation to initiate thermogenic responses in adipose tissue. Remarkably, simultaneous provision of synthetic PPAR γ

agonists with sympathomimetics rescues the compromised adaptive thermogenic response of obesity-prone mice and produces a significant loss of WAT. Coadministration of PPAR γ agonists with sympathomimetics is not required in obesity-resistant mice, as high-fat diets do not compromise their adaptive thermogenic responses. Although the underlying mechanism is not yet known, high-fat diets accentuate leptin resistance by altering the requirement for endogenous PPAR γ agonists to support transcriptional activation of genes involved in adaptive thermogenesis. The consensus at present is that changes in dietary fat content and composition alter synthesis of the endogenous ligands for PPARs in a manner that produces coordinated, integrated transcriptional responses in and among metabolically active target organs. Collectively, the PPARs are viewed as a lipid-based nutrient-sensing system. In the case of adipose tissue, the productive integration of signaling inputs from leptin-induced SNS outflow and lipid-sensitive PPAR activation is required for a full and effective adaptive thermogenic response. A better understanding of the signaling systems, which interact to regulate and limit leptin signaling, is an important missing component in our overall understanding of the mechanisms of energy homeostasis.

Exosomes and Microvesicles

S J Gould, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Published by Elsevier Inc.

Introduction

Animal cells secrete a variety of vesicular particles, from the micron-sized platelets released by megakaryocytes, to smaller vesicles that have the approximate size of virus particles. Several names have been used to describe these smaller vesicles, primarily exosomes and microvesicles. This article discusses our current understanding of the structure of these vesicles, their biogenesis, and their functional significance. While some investigators differentiate between exosomes and microvesicles based on where they are made within the cell, that view is fraught with conceptual, mechanistic, and technical difficulties. For this reason, exosomes and microvesicles will be referred to by the collective acronym of exosome and microvesicle (EMV) in this article, though the term exosome will be used when discussing the classic model of exosome biogenesis.

EMV Structure

EMVs have a limiting bilayer membrane and a proteinaceous lumen. EMVs are commonly claimed to have a density of $\sim 1.15 \text{ g ml}^{-1}$. However, the density of an EMV is primarily a function of their protein:lipid ratio. Not surprisingly, the density of EMVs released by a single cell can be altered by changing the array of proteins being targeted to EMVs. EMVs also lack a unique, defining morphology. For example, EMVs released by human T-cells are fairly uniform in size and shape, but these parameters change dramatically upon expression of a single EMV cargo protein, AcylTyA. In short, EMVs cannot be strictly defined on the basis of density, size, or shape.

EMV Composition: Lipids, Proteins, Carbohydrates, and Nucleic Acids

EMV Lipids

EMVs have a limiting membrane with a bilayer appearance and a high degree of curvature. The phospholipid composition of mammalian EMV membranes is somewhat similar to that of mammalian plasma and endosome membranes, with high levels of phosphatidylcholine ($\sim 50\%$) and phosphatidylethanolamine ($\sim 20\text{--}30\%$), significant amounts of sphingomyelin ($\sim 10\text{--}20\%$), with the remaining portion coming from phosphatidylserine and phosphatidylinositols ($\sim 5\text{--}10\%$). EMVs are also rich in cholesterol, which comprises $\sim 30\%$ of EMV membrane lipid. It has been suggested by some that EMV biogenesis occurs at lipid rafts. However, a direct test of this hypothesis found that EMVs were devoid of several lipid raft markers, undermining the validity of this idea.

EMV Proteins

Like all biological membranes, the limiting membrane of EMVs is rich in proteins (Figure 1). The tetraspanins CD63, CD81, and CD9 are enriched in EMV membranes, as are major

histocompatibility (MHC) proteins, a subset of integrins, and other adhesion molecules such as intercellular adhesion molecule-1 and, in some cases, CD44. EMVs are also enriched for certain GPI-anchored cell-surface proteins such as the complement inhibitory factors CD55 and CD59. EMV membrane proteins also include cytoplasmically oriented proteins anchored to the inner leaflet of the EMV membrane via an acyl moiety (e.g., N-terminal myristoylation) or protein domains that bind to the plasma membrane-enriched phosphoinositides phosphatidylinositol-(4,5)-bisphosphate (PI(4,5)P2) and phosphatidylinositol-(3,4,5)-trisphosphate (PI(3,4,5)P3). These include the Gag proteins of exogenous and endogenous retroviruses, as well as certain synthetic EMV cargoes that have been developed. The outer surface of EMVs can also be decorated with peripheral membrane proteins such as fibronectin, which binds to EMV-anchored $\alpha 4 \beta 1$ integrin, and lactoferrin/MFG-E8, which binds to the phosphatidylserine that is enriched in the outer leaflet of EMVs.

EMVs also include cytoplasmic proteins. Actin and many actin-binding proteins have been identified in purified EMVs, raising the possibility that there might be a role for the cytoskeleton in EMV biogenesis. However, there is as yet no evidence for such a role. In fact, it is not even clear whether these cytoskeletal proteins are selectively targeted to EMVs, or merely incorporated passively during vesicle formation. A similar phenomenon of unselective incorporation might explain the detection of many other cytoplasmic (and membrane) proteins identified in proteomic analyses of purified EMVs (>2000 at last count). One of the more intriguing sets of cytoplasmic EMV cargoes are members of the endosomal sorting complexes required for transport (ESCRT) machinery, as TSG101, VPS28, and Alix are significantly enriched in EMVs. Although there is no set of proteins that defines exosome or microvesicles from one another or from the cell (a result that likely reflects the stochastic nature of the EMV biogenesis pathway), several proteins serve as reasonably reliable markers of EMVs. These include the tetraspanins CD63 and CD81 and the ESCRT-associated proteins TSG101 and Alix.

EMV Carbohydrates

The carbohydrate composition of EMVs is presumed to reflect that of the glycoproteins and glycolipids found on their surface. Unfortunately, the high degree of cell-to-cell variation in carbohydrate moieties, even among human T-cell lines, results in a corresponding cell-to-cell variation in the lectin-binding properties of EMVs. Thus, while there does appear to be a specific enrichment of certain carbohydrates in EMVs (e.g., high mannose), EMVs lack a unique carbohydrate signature.

EMV Nucleic Acids

A major advance in EMV biology was the finding that secreted vesicles contained significant amounts of nucleic acids,

Figure 1 Major proteins of the EMV. EMVs contain a diverse array of proteins, including integral membrane proteins (e.g., CD63, CD81, MHC proteins, integrins, CD44), GPI-anchored proteins (e.g., CD55), outer peripheral membrane proteins (e.g., MFG-E8), inner peripheral membrane proteins (e.g., Gag), and cytosolic proteins that associate directly or indirectly with the inner leaflet of the plasma and endosome membranes (e.g., ezrin, actin, TSG101, VPS28, Alix).

particularly RNAs. Importantly, it has been demonstrated that EMV-enclosed RNAs can be transferred from cell to cell and that EMV-delivered messenger RNAs (mRNAs) and microRNAs (miRNAs) can alter gene expression in the recipient cell. As for the profile of RNAs present in secreted vesicles, there is a strong bias toward small RNAs (miRNAs and other small noncoding RNAs) and away from mRNAs and large ribosomal RNAs. There is also emerging evidence that some cells target specific miRNA families to EMVs.

EMV Biogenesis: A Prominent Role for the Plasma Membrane

The classic model of exosome biogenesis invokes (1) the selective targeting of exosomal proteins to the limiting membrane of endosomes, (2) the enrichment of exosomal proteins at endosomal sites of vesicle budding, (3) the inclusion of exosomal proteins in the intraluminal vesicles of discrete endosomes/multivesicular bodies (MVBs), and (4) the subsequent vesicular secretion of exosomal proteins when MVBs fuse with the plasma membrane. However, several tests of this hypothesis have generated anomalous rather than supporting data for this classical model of exosome biogenesis. For example, a wide variety of exosomal proteins and exosomal lipids are enriched at discrete domains of the plasma membrane in human T-cells, which also serve as sites for exosome budding. In addition, a search for *cis*-acting signals that target proteins to exosomes revealed that a wide variety of plasma membrane anchors can target proteins to exosomes, but that endosomal membrane anchors cannot. Furthermore, inhibitors of ESCRT function block MVB biogenesis but have no effect on the budding of exosomal cargoes. Finally, it has been established

that macrophages (and other cell types thought to bud exosomes from MVBs) possess deep invaginations of the plasma membrane that have an MVB-like morphology, and that budding into these structures might be mistaken for budding into bona fide MVBs. Based on these and other observations, it appears that the plasma membrane plays a more prominent role in exosome biogenesis than previously believed, and that the endosome membrane might play a less important role than currently assumed.

EMV Biogenesis: *trans*-Acting Factors

Another way to shed light on the mechanisms of EMV biogenesis is to identify *trans*-acting factors that are essential for vesicle production. Over the past decade, several proteins have been implicated in the production of secreted vesicles. These include Rab 11, 35, and 27, though the exact roles of these proteins in EMV biogenesis remain obscure. Ceramide has also been implicated in the vesicular budding of some EMV cargoes, raising the possibility that lipid composition might also contribute to EMV biogenesis. However, it is still unclear whether these factors play direct roles in EMV biogenesis or whether they act upstream of EMV biogenesis in the sorting of cargo proteins to sites of EMV biogenesis.

Cellular Functions of EMV Biogenesis

A major facet of EMV research is to understand how the formation of EMVs benefits the EMV-producing cell. Perhaps the most obvious role of EMV biogenesis is in protein (and lipid?) quality control at the plasma membrane. This involves both the targeted elimination of specific plasma membrane proteins during specific developmental processes and the continual elimination of aggregated plasma membrane proteins under steady-state conditions. The EMV biogenesis pathway also appears to play critical roles in cell polarity: in both human lymphocytes and protozoan social amoeba, the EMV protein-sorting pathway is responsible for targeting proteins to their posterior pole, or uropod. Furthermore, it has been shown that elevated levels of EMV cargo proteins polarize the EMV protein-sorting pathway, drive the formation of a nascent posterior pole, and prime the cell for the subsequent morphological and functional development of the posterior pole, as occurs during uropod formation.

EMV-Mediated Effects on Neighboring Cells

The physiological significance of EMV biology extends to neighboring cells. For example, EMVs have been reported to play numerous roles in immunological signaling, such as during antigen presentation, and the induction of dietary tolerance. EMVs have also been implicated in signaling from somatic epithelium to developing germ cells during sperm maturation, in the transport of morphogens during development, in neuronal signaling, and in the modulation of stem cell fate. The molecular mechanisms underlying these signaling events are still under investigation. EMVs transmit some of their signals by contact between EMV surface molecules and

their cognate receptors on the surface of neighboring cells. However, there is increasing evidence that EMVs can transmit signals to neighboring cells through a process of EMV:cell fusion, delivering molecules from the membrane and cytoplasm of donor cells into the membrane and cytoplasm of recipient cells. Clear evidence for this comes from the EMV-mediated transfer of activated epidermal growth factor receptor, as well as from the EMV-mediated transfer of RNAs.

EMVs and Human Disease

EMVs have been implicated in a wide range of human diseases, including human immunodeficiency virus (HIV) infection. Specifically, it has been proposed that HIV (and other retroviruses) use the preexisting, nonviral mechanism of EMV biogenesis for the production of infectious particles. In support of this hypothesis, it has been shown that: (1) EMVs and retrovirus particles have a similar molecular composition; (2) retroviral proteins are targeted to sites of EMV budding and secreted from the cell in EMVs; (3) higher-order oligomerization and plasma membrane binding target proteins to both EMVs and to HIV particles; (4) higher-order oligomerization and plasma membrane binding are the primary budding information in HIV Gag; and (5) retroviruses use the same types of plasma membrane anchors that are the most efficient at inducing the EMV targeting of nonviral proteins (i.e., an N-terminal myristoylation tag or a PIP2-binding domain).

The roles of EMVs in cancer are less direct but potentially more complex. Cancer-derived EMVs are thought to be mediators of immunosuppressive environments, potentiating the apoptosis of activated, cytotoxic, anti-cancer T-cells, impairing the differentiation of monocytes into dendritic cells, and inducing myeloid-suppressive cells and T-regulatory cells. Moreover, such EMVs are found not only within the cancer but also in the circulating fluids of the cancer patient, raising the possibility that tumor-derived EMVs might prime the body for subsequent spread of metastatic tumor cells. In addition, cancer-derived EMVs have been shown to be enriched in doxorubicin and perhaps other anti-cancer drugs, raising the possibility that EMVs might be a significant route for cancer drug resistance.

The role of EMVs in human disease also extends to several neurological disorders. The most obvious is in prion-based amyloidopathies where the normal cellular prion protein, PrP^C, is normally sorted to sites of EMV biogenesis and secreted from the cell in EMVs. Intriguingly, this appears to also hold true for the pathogenic form of the protein, PrP^{Sc}, suggesting that EMVs might facilitate the spread of disease within the body, and perhaps between individuals. In addition, it has been proposed that EMVs might also be involved in the release and spread of 'prionoids' that are implicated in Alzheimer's disease, Parkinson's disease, Huntington's disease, etc.

Conclusion

This article demonstrates the significant strides that have been made in understanding the structure and function of exosome and microvesicles, the fascinating biological potential of the intercellular vesicle trafficking pathway defined by these secreted organelles, and the continuing efforts to elucidate the modes and mechanisms of vesicle secretion. The accomplishments of the past decade bode well for a rapid resolution of the most pressing questions in the field as well as for new discoveries about how EMVs contribute to the biology of animal cells and the complex organisms they comprise.

Glossary

Activation loop A region within protein kinase catalytic domains that is often phosphorylated to promote catalytic activity.

Integrins A large family of cell surface adhesion receptors, composed of α - and β -subunits, which link the extracellular matrix to the actin cytoskeleton and transmit biochemical signals across the plasma membrane.

Src-homology 2 (SH2) A domain that mediates protein–protein interactions by binding to sites of tyrosine phosphorylation.

Src-homology 3 (SH3) A domain that mediates protein–protein interactions by binding to proline-rich motifs with a core sequence of Pro-X-X-Pro.

Tyrosine kinase A kinase that phosphorylates protein substrates on tyrosine residues.

Focal Adhesion Kinase

Focal adhesion kinase (FAK) ([Figure 1](#)) was the first member of the family to be described, in 1992, and has been most extensively studied. Its name derives from its prominent localization to focal adhesions observed in cultured fibroblasts ([Figure 2](#)). Focal adhesions are sites where cell surface integrins cluster and make strong adhesive contact with components of the extracellular matrix (ECM) such as fibronectin, vitronectin, and collagen. Focal adhesion localization was the first indication that FAK has a signaling function in regulating aspects of cell behavior in response to integrin-mediated adhesion. The focal adhesion targeting (FAT) domain is necessary and sufficient for focal adhesion localization. The FERM domain (4.1 protein, ezrin, radixin, and moesin (FERM)) acts as a negative-regulatory element by interacting with and inhibiting the kinase domain. Signaling by FAK requires release of this autoinhibition, which involves conformational change triggered by contractile tension generated at the focal adhesions. Hence, FAK can act in the process of mechanotransduction whereby cellular signaling events are initiated in response to mechanical forces.

FAK Expression and Roles in Development

FAK is widely expressed throughout embryogenesis and functions in many developmental processes. FAK-deficient mouse embryos fail to develop past late stages of gastrulation, and exhibit dramatically retarded development of the antero-posterior axis, suggestive of defects in mesodermal migration. Studies using late-stage embryos from mouse, *Xenopus*, and zebrafish indicate high FAK expression associated with several developing systems, including the central nervous system,

somites, arterial walls, myotendinous junctions, and germ cells. FAK is ubiquitously expressed in adult tissues, with high levels found in brain, lung, and testis. In neuronal cells, FAK is enriched in growth cones. Neuronal FAK is expressed from alternatively spliced transcripts resulting in short insertions in the region between the FERM and kinase domains. Targeted knockout studies in mice have demonstrated critical roles for FAK in development of the heart, vascular network, and nervous system.

FAK Activation and Signaling

Like most tyrosine kinases, FAK is in its active signaling state when phosphorylated on tyrosine residues. FAK tyrosine phosphorylation results from integrin-mediated cell adhesion to the ECM and is maintained by Rho-mediated contraction of the actin cytoskeleton. The initial step in FAK activation is phosphorylation of Tyr-397, which occurs through intermolecular autophosphorylation. Neuronal-specific isoforms of FAK have a higher intrinsic capacity to autophosphorylate. A crucial aspect of FAK signaling is the recruitment of Src-family kinases, which bind via their SH2 domains to the phosphorylated Tyr-397 site. This leads to Src-mediated phosphorylation of other FAK tyrosine residues: 576, 577, 861, and 925 ([Figure 1](#)). Tyrosines 576 and 577 reside in the kinase domain activation loop, and phosphorylation of these sites elevates catalytic activity. Phosphorylated Tyr-925 can bind the SH2 domain of the adaptor protein Grb2, suggesting a mechanism for integrin stimulation of extracellular-signal regulated kinase (ERK) via a FAK > Grb2/SOS > Ras pathway. Tyr-925 lies buried in the FAT domain such that phosphorylation of this residue may occur only upon a structural alteration of the FAT

domain that would also release FAK from focal adhesions. The signaling function of the Tyr-861 site is uncertain.

Src-family kinases recruited to the Tyr-397 site also phosphorylate two FAK-associated proteins: Crk-associated substrate (p130Cas) and paxillin. P130Cas, via its SH3 domain, interacts with either of two proline-rich motifs (PR1 and PR2) that reside in the region linking the kinase and FAT domain. Paxillin interacts with the FAT domain. For both p130Cas and paxillin, the major tyrosine phosphorylation sites are in Tyr-X-X-Pro (YxxP) motifs. Phosphorylation of YxxP sites promotes downstream signaling events through recruitment of additional SH2-containing effector molecules, notably adaptor proteins of the Crk and Nck families. In addition to Src family kinases, the phosphorylated Tyr-397 site mediates interactions with SH2 domains of other signaling proteins including phosphatidylinositol 3-kinase (PI3K), the γ 1 isoform of phospholipase C (PLC- γ 1), Shc, Grb7, and Nck-2. Thus, FAK likely promotes assembly of several distinct signaling complexes within a larger integrin-associated protein network.

Figure 1 Representative members of the FAK family. FAK and PYK2 (represented by the human proteins) are the two vertebrate family members. Also shown are the homologs from *Marsupenaeus japonicus* (Shrimp FAK), *Lytechinus variegatus* (Sea urchin FAK), *Drosophila* (Fly DFak56), and *Caenorhabditis elegans* (Worm KIN32). Shown in the linear structures are major conserved domains, protein interaction motifs (PR1 and PR2), and sites of tyrosine (Y) phosphorylation. The scale bar represents number of amino acid residues.

Figure 2 Localization of FAK in focal adhesions. Primary cultures of mouse keratinocytes were plated on fibronectin and stained using an antibody against FAK. The highly immunoreactive structures observed at the cell peripheries are focal adhesions.

Cellular Responses to FAK Signaling

FAK signaling promotes cell migration. For example, fibroblasts derived from *FAK*^{-/-} mouse embryos exhibit poor motility compared to cells from normal embryos, and the defect can be rescued by re-expressing wild-type FAK, but not by signaling-deficient FAK mutational variants (i.e., lacking the Tyr-397 autophosphorylation site). The cell motility response to FAK signaling is due to defects in focal adhesion disassembly and organization of lamellipodia at the protruding leading edge. FAK signaling also promotes activation of matrix-degrading metalloproteinases, thus stimulating the ability of cells to invade through the ECM.

In addition to motility and invasion, FAK functions as a positive regulator of cell growth by triggering both survival and proliferative signals. FAK-mediated signaling confers resistance to apoptosis resulting from various stimuli, including loss of anchorage to the ECM (anoikis), oxidative stress, ultraviolet (UV) irradiation, and exposure to anticancer drugs. FAK survival signals can result from multiple downstream events, including p130CAS/Crk complex formation, resulting in PI3K-mediated activation of Akt. FAK may also help drive progression through G1 phase of the cell cycle through its ability to activate ERKs and promote transcriptional activation of the gene encoding cyclin D1. FAK expression and activity are commonly elevated in human cancers, making FAK a potentially important target in the therapeutic treatment of these diseases.

Proline-Rich Tyrosine Kinase 2

Proline-rich tyrosine kinase 2 (PYK2) is also known as cellular adhesion kinase β (CAK- β), related adhesion focal tyrosine kinase (RAFTK), and calcium-dependent tyrosine kinase (CADTK). The FAT and kinase domains of PYK2 each exhibit 60% amino acid identity with the homologous domains of FAK, while the FERM domain is less conserved (Table 1). Both PR motifs in the kinase-FAT linking region are present in PYK2 (and capable of mediating interactions with p130Cas), but otherwise this region is poorly conserved, as is the short region amino-terminal to the FERM domain. Four tyrosine residues corresponding to sites of FAK phosphorylation are functionally conserved (Figure 1): phosphorylated Tyr-402 mediates interactions with Src-family kinases, phosphorylated activation loop tyrosines 579 and 580 stimulate PYK2 catalytic activity, and phosphorylated Tyr-881 binds Grb2.

PYK2 Activation and Signaling

Like FAK, PYK2 activation can result from integrin stimulation. For example, PYK2 undergoes tyrosine phosphorylation

Table 1 Conservation of FAK family domains^a

	PYK2	DFak56	KIN-32
FERM	45	29	25
KINASE	60	63	51
FAT	60	44	19

Human PYK2 was used for the comparison.

^aPercent amino acid identities are shown compared to human FAK.

following plating of megakaryocytes onto fibronectin and upon antibody stimulation of B-cell integrins. In fibroblasts, PYK2 is detected in focal adhesions, consistent with the high conservation of the FAT domain. It is notable, however, that the FAT domain of PYK2 targets to focal adhesions inefficiently compared to that of FAK. PYK2 activation in response to integrin-mediated adhesion has been observed in *FAK*^{−/−} fibroblasts. But re-expression of FAK in these cells effectively suppresses the PYK2 response, probably by displacing PYK2 from the adhesion sites. These observations suggest that PYK2 may not play as widespread a role in integrin signaling as does its sister molecule, FAK.

In contrast to FAK, PYK2 can be activated to autophosphorylate on Tyr-402 by extracellular signals that elevate levels of intracellular calcium and stimulate calcium-dependent isoforms of protein kinase C. These include agonists for G-protein-coupled receptors, voltage-gated calcium channels, and the nicotinic acetylcholine receptor. The mechanisms by which calcium and/or protein kinase C activate PYK2 remain poorly understood. The downstream signaling events resulting from PYK2 activation are generally similar to those of FAK, involving recruitment of Src family kinases to the autophosphorylation site, and Src-mediated phosphorylation of other sites on PYK2 as well as PYK2-associated p130Cas and paxillin (Figure 3). The interaction of Grb2 with the PYK2 Tyr-881 site provides a link between G-protein-coupled receptors and ERK activation.

Cellular Responses to PYK2 Signaling

Unlike FAK, PYK2 overexpression does not efficiently promote fibroblast motility, and results in apoptosis rather than cell survival. Nevertheless, a crucial role for PYK2 in the motility and migration of macrophages and B cells has been demonstrated using cells derived from PYK2-deficient mice. Defects in

lymphocyte motility could explain the absence of marginal zone B cells in these animals. Through its ability to be activated by both integrin- and calcium/PKC-dependent mechanisms, PYK2 can function in numerous and diverse signaling pathways regulating a wide variety of cellular activities. In neuronal cells, PYK2 has been implicated as a positive regulator of neurite outgrowth and *N*-methyl-D-aspartate (NMDA) channel activity. Other consequences of PYK2 signaling include inhibition of voltage-gated potassium channels leading to membrane depolarization of vascular smooth muscle cells, translocation of the glucose transporter type 4 (GLUT4) to the plasma membrane of adipocytes, stimulation of Na-HCO^{3−} cotransporter activity in renal epithelial cells, and angiogenesis of vascular endothelial cells. In small-cell lung cancer, activation of PYK2 is involved in neuropeptide-stimulated cell survival and proliferation.

Invertebrate Members of the FAK Family

Drosophila and *Caenorhabditis elegans* genomes each contain a single member of the FAK family: DFak56 in *Drosophila* and KIN32 in *C. elegans*. Sea urchin and shrimp FAK homologs have also recently been described. FAK and PYK2 are more closely related to one another than they are to any of the invertebrate homologs, indicating that the two vertebrate family members arose through gene duplication after evolutionary separation from the invertebrates.

Drosophila DFak56 shows overall conservation with the two vertebrate family members, but is slightly more similar to FAK than to PYK2. The kinase domain of DFak56 is most highly conserved in comparison to FAK, followed in order by the FAT domain and the FERM domain (Table 1). Within the kinase-FAT linker region, DFak56 contains a proline-rich motif corresponding to the PR1 site, but lacks the PR2 site. Of the six sites of FAK tyrosine phosphorylation, DFak56 lacks only the site corresponding to FAK Tyr-861. However, DFak56 Tyr-962, which corresponds to the Grb2-binding sites in FAK and PYK2, lacks the asparagine residue at the +2 position, which is part of the consensus sequence for Grb2 SH2 binding. A unique structural feature of DFak56 is an extended carboxyl-terminal region. Like the vertebrate members of the FAK family, DFak56 exhibits autophosphorylation activity and undergoes tyrosine phosphorylation in response to integrin-mediated adhesion. DFak56 is broadly expressed during embryogenesis, with strongest expression in the developing gut, central nervous system, and muscle. Null mutations of the *DFAK56* gene have been linked to defects in optic stalk formation by glial cells of the visual nervous system and to overgrowth of larval neuromuscular junctions. Given the embryonic lethal phenotype of the mouse FAK knockout, it is somewhat surprising that flies lacking DFak56 do not have more dramatic developmental defects. The activity of DFak56 in restricting neuromuscular junctions' synaptic elaboration was associated with ERK inhibition, further indicating differences in signaling functions of vertebrate and invertebrate FAK-family kinases.

C. elegans KIN32 contains a well-conserved kinase domain, while both the FAT and FERM domains are rather poorly conserved in comparison to other members of the FAK family

Figure 3 Signaling by FAK and PYK2. Both FAK and PYK2 can be activated by integrin-mediated adhesion, while PYK2 is uniquely activated through a calcium/PKC-dependent mechanism. A critical element of FAK and PYK2 signaling involves the recruitment of Src family kinases to sites of autophosphorylation (Tyr-397 for FAK and Tyr-402 for PYK2). The associated Src family kinases may then phosphorylate a conserved FAK/PYK2 tyrosine site to promote Grb2 binding, and also phosphorylate FAK/PYK2-associated proteins including p130Cas and paxillin to promote downstream signals such as those mediated by Crk SH2/SH3 adaptor proteins. Grb2 and Crk interact with guanine-nucleotide exchange factors leading to the activation of small G proteins Ras and Rac, respectively.

(Table 1). Interestingly, KIN32 lacks key motifs associated with signaling by FAK-family kinases including a tyrosine corresponding to the autophosphorylation site and proline-rich motifs in the kinase-FAT linker region, suggesting a divergent signaling function. KIN32 is expressed in all larval stages and is prominent in body wall muscle cells. As is the case for *Drosophila* DFak56, there is no obvious phenotype associated with a deletion of the gene encoding *C. elegans* KIN32.

F-ATPases

J E Walker, The Medical Research Council Mitochondrial Biology Unit, Cambridge, UK

© 2013 Elsevier Inc. All rights reserved.

Glossary

Oligomycin and the OSCP subunit Oligomycin is an antibiotic that inhibits the proton-pumping activity of the F-ATPase in mitochondria, but not in eubacteria or chloroplasts. In *Saccharomyces cerevisiae*, oligomycin-resistant mutants map to the F_o subunits, a and c, indicating that the site of action of the antibiotic is probably in the region of their interface. However, the name of the OSCP subunit, or in full, the oligomycin sensitivity conferral protein, often leads to the erroneous assumption that this subunit provides the site of binding of the antibiotic. The name of the OSCP derives historically from reconstitution experiments in which the separate mitochondrial F_1 domain was reassembled onto inner membrane vesicles from bovine heart mitochondria lacking the F_1 domain. It was found that in order to reassemble a fully functional proton-pumping F-ATPase and thereby regain the sensitivity of its activity to the action of oligomycin, other protein factors had to be added also. One of these factors was named the OSCP in recognition of the necessity for its presence in the reassembled enzyme in order to regain sensitivity to the antibiotic, and the other was named simply as factor 6, or F_6 . Today, we know that both of these proteins are essential components of the peripheral stalk of the mitochondrial F-ATPase. In an enzyme assembly lacking either of them, ATP synthesis or hydrolysis is uncoupled from proton translocation through the F_o membrane domain, and is insensitive to the action of oligomycin in the F_o domain.

Proton-motive force The term trans-membrane proton-motive force (pmf or Δp) was coined by the

British biochemist and Nobel Laureate, Peter Mitchell, as a way of describing the proton electrochemical gradient, $\Delta \tilde{\mu}_{H^+}$, that is built up across an energy-transducing membrane by respiration or photosynthesis. It has two components, the membrane potential difference across that membrane, $\Delta\psi$, and the pH difference across that membrane, ΔpH . The pmf is expressed in units of voltage. At 25 °C: Δp (in mV) = $\Delta\psi - 59 \Delta pH$.

Subunit equivalence The nomenclatures of subunits of F-ATPases from eubacteria, chloroplasts, and mitochondria have evolved somewhat independently, creating the potential for confusion and misunderstanding. The terms α -, β -, and γ -subunits denote equivalent subunits in all F-ATPases. However, the equivalent subunits in mitochondria of the eubacterial and chloroplast δ - and ϵ -subunits are, respectively, the OSCP and the δ -subunit. Eubacterial and chloroplast F-ATPases do not contain a subunit that is equivalent to the mitochondrial ϵ -subunit. In chloroplast F-ATPases, subunits a, b, b', and c are sometimes referred to as subunits IV, II, I, and III, respectively, and in the mitochondrial enzyme subunit a is sometimes referred to as ATPase-6 or A6. For details of nomenclature of peripheral stalk subunits and supernumerary subunits in mitochondrial F-ATPases, see also the legend to [Figure 1](#).

The P/O ratio By convention in bioenergetics, O refers to $1/2O_2$, which is equivalent to two electrons. The P/O ratio is the number of moles of ADP phosphorylated to ATP per two electrons transferred to oxygen.

Introduction

The F-ATPases, also known as F_1F_o -ATPases, are multisubunit enzyme complexes found in energy-transducing membranes in eubacteria, mitochondria, and chloroplasts. Their role is to synthesize adenosine triphosphate (ATP) from adenosine diphosphate (ADP) and phosphate under aerobic conditions using a proton-motive force, Δp , generated by respiration or photosynthesis, as a source of energy. The ATP hydrolase activities of the enzymes from mitochondria, chloroplasts, and some eubacteria are inhibited, and these enzymes can only synthesize ATP. However, some other eubacterial enzymes can hydrolyze ATP, made by glycolysis under anaerobic conditions, to generate the Δp that is required for other essential cellular functions, such as chemotaxis and transmembrane transport processes. The F-ATPases are close relatives of the V-ATPases (vesicular ATPases) found in secretory membranes that use the energy from ATP hydrolysis to generate ion gradients across those membranes, and of the A-ATPases that make ATP in the archaea. This article focuses on the structure and

function of the F-ATPases. Some eubacteria generate a sodium ion-motive force that is coupled to ATP synthesis, and the structures and functions of these F-ATPases are broadly similar to the F-ATPases that are driven by Δp .

Structure of F-ATPases

Irrespective of their source, F-ATPases have related structures, as summarized in [Figure 1](#). They consist of two major functional domains, a membrane extrinsic F_1 sector and a membrane intrinsic F_o sector joined together by central and peripheral stalks. The F_1 domain is the catalytic part of the enzyme where ATP, the energy currency of the biological world, is formed from ADP and inorganic phosphate. The F_o domain contains a motor, which generates rotation using the potential energy stored in Δp , as explained in [Figure 2](#). The rotational energy of the motor is transmitted to the catalytic domain by the central stalk, which is attached directly to the rotary motor. Thus, the enzyme is analogous to a turbine in an

Figure 1 The organization of protein subunits in F-ATPases. The eubacterial and chloroplast F-ATPases are depicted on the left, and the more complex mitochondrial F-ATPase is on the right. The upper part of each model contains the subunits in the F_1 catalytic domain. One of the three α -subunits (red) has been removed to expose the elongated α -helical structure in the γ -subunit (dark blue), which lies approximately along the central axis of the $\alpha_3\beta_3$ domain. The γ -subunit (and associated subunits) is in contact with the F_0 membrane domain, which contains the c-ring (brown) and the associated a-subunit (gray). The number of c-subunits in the c-ring differs between species. The rotor of the enzyme consists of the ensemble of the c-ring and the γ -subunit (and associated subunits). The pathway for protons through the F_0 domain is in the vicinity of the interface between the c-ring and a-subunit. The peripheral stalk is on the right of each model. In some eubacterial enzymes, it consists of the δ -subunit (light blue) and two identical b-subunits (pink). In other eubacterial enzymes, and in the chloroplast enzyme, the two b-subunits are replaced by single copies of homologous, but nonidentical, subunits b and b'. The N-terminal domain of the δ -subunit binds to the N-terminal region of one of the three α -subunits, and the b- and b'-subunits interact with the a-subunit via their N-terminal transmembrane α -helices. In the mitochondrial enzyme, the peripheral stalk consists of single copies of subunits OSCP, b, d, and F_6 . The OSCP is the homolog of the bacterial δ -subunit. The sequences of mitochondrial subunits b, d, and F_6 are not evidently related to those of the bacterial b- and b'-subunits. Their structures also differ significantly, although they are both dominated by α -helices, except for the C-terminal domain of the OSCP (and presumably the eubacterial and chloroplast δ -subunit), which contain β -structures. The membrane domains of the mitochondrial enzyme contain a number of membrane subunits with single transmembrane spanning α -helices that are not found in eubacteria and chloroplasts. These supernumerary subunits have no known roles in the generation of ATP; subunits e, f, g, and A6L are indicated, and subunits DAPIT and the 8 kDa proteolipid, which are found in the complex when phospholipids are maintained during the purification of the complex, are not shown.

electric power station, which uses the potential energy of water stored in a dam to generate rotation in order to produce electricity, the energy currency of the man-made world.

The F_1 domain of the F-ATPase is an assembly of five globular proteins, α , β , γ , δ , and ϵ with the stoichiometry $\alpha_3\beta_3\gamma_1\delta_1\epsilon_1$. Their combined molecular weight is around 350 kDa. The $\alpha_3\beta_3\gamma_1$ subassembly is common to all F-ATPases. The three α - and the three β -subunits form an approximately spherical $\alpha_3\beta_3$ structure about 100 Å in diameter with the six subunits arranged in alternation around an elongated α -helical structure found in the γ -subunit. This part of the γ -subunit is completely enveloped in the $\alpha_3\beta_3$ domain and occupies its central axis. Thus, the $\alpha_3\beta_3$ structure resembles an orange made of six segments arranged around the central pith stalk of the fruit. The rest of the γ -subunit protrudes about 30 Å beyond the $\alpha_3\beta_3$ domain and forms part of a foot that attaches the $\alpha_3\beta_3\gamma_1$ complex firmly to the F_0 domain. This attachment is augmented by another protein, known for historical reasons as the ϵ -subunit in eubacteria and chloroplasts and as the δ -subunit in mitochondria. Despite their different names, these ϵ - and δ -subunits are folded and probably bind in a similar way, and their functions are probably related also, although they are not identical. In mitochondria, the attachment of the foot of the γ -subunit to the F_0 domain is

augmented by a second subunit. Known confusingly as the ϵ -subunit, this mitochondrial protein has no counterpart in eubacterial and chloroplast enzymes. The γ -subunit, and the associated ϵ -subunits in the eubacterial and chloroplast enzymes, and the associated δ - and ϵ -subunits in the mitochondrial enzyme, are bound firmly to one end of a hydrophobic cylindrical structure in the F_0 membrane domain of the enzyme. This cylinder, together with the γ -subunit and its associated ϵ - and δ -subunits, forms the rotor of the enzyme.

The cylinder is made of c-subunits, simple membrane proteins folded into two transmembrane α -helices, with the loop regions joining the α -helices exposed on the same side of the membrane as the F_1 domain, and with some of the loops at least in contact with, and binding to, the foot of the central stalk. The N-terminal α -helices of c-subunits form the core of the cylinder, and the C-terminal α -helices provide its external annulus. Most importantly for the generation of rotation of the rotor from the proton-motive force, each c-subunit contains an essential acidic amino acid residue (aspartate or glutamate depending on the species) placed at the mid-point of the membrane domain of the enzyme. The number of c-subunits that form the hydrophobic cylinder is not constant throughout the biological world. Vertebrates (about 50 000 species) have eight c-subunits arranged in their cylindrical ring structures,

Figure 2 The generation of rotation in the F_0 membrane domain of F-ATPases. The a-subunit (green) is shown in contact with the cylindrical ring of c-subunits (blue). The C-terminal α -helix of each c-subunit contains a carboxyl (in the side chain of an aspartate or glutamate residue; dark blue circles) exposed on the external circumference of the cylinder. From the bottom of the figure, protons from the side of the membrane distal from the F_1 domain of the F-ATPase are shown entering a half-channel and neutralizing a negatively charged carboxylate in the interface between the a-subunit and the c-ring. Once neutralized, this residue moves by Brownian motion to the more hydrophobic environment of the lipid bilayer generating a rotation in the direction indicated. This rotational step brings another negatively charged carboxylate into the lower half-channel allowing another proton to be consumed, generating another rotational substep. Thus, as more negative charges are neutralized by protons, the protons are carried around on the external surface of the ring by the neutralized carboxyl, until they reach a second site in contact with the a-subunit, where the local environment reionizes the carboxyl, releasing the proton through a second half channel on the opposite of the membrane from which it entered. The direction and magnitude of Δp (~ 180 mV inwards in mitochondria) ensure that the rotation is unidirectional, and there is no requirement for a ratchet mechanism. The number of protons required to generate each 360° rotation of the c-ring corresponds to the number of c-subunits that form the ring. The γ -subunit (and associated subunits) are attached firmly to the ring, and each 360° rotation of this part of the rotor provides the energy to generate three molecules of ATP from the F_1 domain (see below).

and invertebrates (about 2 million species) probably have c_8 -rings as well. Hence, the c_8 -feature is probably found in F-ATPases throughout the multicellular biological world. By contrast, unicellular organisms, including fungi and eubacteria (and also chloroplasts from green plants), have a variety of different numbers of c-subunits in their c-rings, and values of 9, 10, 11, 13, 14, and 15 have been reported. These values are highly significant in the consideration of the energy cost to the cell in making each molecule of ATP (see later).

During ATP synthesis, the rotation of the ring is driven by the proton-motive force in a clockwise direction (as viewed from the membrane domain toward the F_1 domain), with an estimated rotary speed of about 100–150 revolutions per second, depending on the species. In the F-ATPases that hydrolyze ATP under anaerobic conditions, the energy to drive rotation is now provided by the hydrolysis of ATP, which drives the rotor in a counterclockwise direction, and pumps protons across the energy transducing membrane in the outward direction (away from the F_1 domain of the enzyme), thereby generating the trans-membrane Δp . The c-ring is in contact with, and rotates against, the surface of another hydrophobic membrane protein, known variously as subunit a (in eubacteria), ATPase-6 or A6 (in mitochondria) and subunit IV (in chloroplasts). For simplicity, here it will be referred to as subunit a. Little is known about the structure of this protein, except that it contains a basic amino acid (arginine-210 in the protein from *Escherichia coli*) that participates in the translocation of protons

through the F_0 membrane domain of the enzyme. It is likely that this protein provides a pathway (a channel or two half channels) to allow protons to access the negatively charged carboxylate residues on the C-terminal α -helices of c-subunits on the external surface of the c-ring in the rotor, and, following neutralization of the successive carboxylates, rotation of the ring, and successive reionization of the carboxylates, to allow the protons to be released on the opposite side of the F_0 domain. The protein is joined to the external surface of the $\alpha_3\beta_3$ domain by the peripheral stalk, an elongated and largely α -helical structure that extends from the F_0 membrane domain to the topmost extremity of the F_1 -domain, where it binds to the N-terminal region of an α -subunit. The role of the peripheral stalk is to counter the tendency of the $\alpha_3\beta_3$ domain to follow the rotation of the rotor, and its integrity is essential for Δp to be coupled to ATP synthesis.

How ATP Is Made in the F_1 Domain

The understanding of the mechanism of how ATP is synthesized in the catalytic F_1 domain of the enzyme is based on a series of high-resolution structures determined by X-ray crystallography with the bovine and yeast enzymes. Many of them represent the ground state in the catalytic cycle either of ATP hydrolysis or synthesis, or of the closely related ADP-inhibited state. One such structure is summarized in [Figure 3](#).

In these structures, the three noncatalytic α -subunits and the three catalytic β -subunits of the enzyme are arranged in alternation around an asymmetric α -helical structure in the single γ -subunit. The α - and β -subunits are similar, each consisting of an N-terminal domain with six β -strands, a central nucleotide-binding domain made of both α -helices and β -strands, and an α -helical C-terminal domain containing six α -helices in β -subunits and seven in α -subunits. Because the γ -subunit is asymmetrical, F₁-ATPase is an inherently asymmetrical enzyme, and a structure of yeast F₁-ATPase without bound nucleotides demonstrated that the asymmetry is derived from the protein assembly itself. The asymmetry of the single γ -subunit obliges each of the three catalytic β -subunits to adopt a different conformation with different nucleotide binding and catalytic properties. Two of them have similar conformations, but in one structure, now recognized as the ADP-inhibited state of the enzyme (see section [Regulatory Mechanisms](#)), one subunit designated as β_{DP} contains bound ADP-Mg, and the second subunit, β_{TP} , has bound AMP-PNP-Mg (adenylylimidodiphosphate is a nonhydrolyzable analog of ATP). However, in other structures, which represent the ground state of the active catalytic cycle, two molecules of AMP-PNP-Mg, ADP-BeF-Mg, or ADP-Mg are bound to both β_{TP} - and β_{DP} -subunits in the same structure. Hence, the β_{DP} - and β_{TP} -subunits can bind either ADP or ATP. In all of these structures, the third subunit, the β_E -subunit, adopts a radically different conformation, in which part of the nucleotide-binding domain and the attached C-terminal domain have hinged outward together, in response to the curvature of the γ -subunit. In these structures, this β -subunit has no bound nucleotide, and so it is known as the empty or open state, designated as β_E . None of the α -subunits open in a similar way. All three of them remain closed, each binding a magnesium ion and a nucleotide, and they remain bound throughout the catalytic cycle. The nucleotides bound to α -subunits have no direct role in the formation of ATP. Other intermediate states in the catalytic cycle have been resolved by X-ray crystallography most notably, a transition-state analog structure, where the catalytic cycle has been arrested before the release of ADP-Mg from the β_E -subunit.

In order to explain the interconversion of catalytic sites through tight, loose, and open states required by a binding change mechanism of catalysis of ATP hydrolysis by F₁-ATPase, it was proposed that the interconversion of sites was effected by a mechanical rotation of the γ -subunit, each 360° rotation taking each β -subunit through the three states represented by the β_{TP} -, β_{DP} -, and β_E -subunits, thereby hydrolyzing three ATP molecules. It was shown subsequently by biophysical experiments conducted with single enzyme complexes that during ATP hydrolysis, in either a bacterial $\alpha_3\beta_3\gamma$ complex or the intact F₁F₀-ATPase, the direction of rotation was counterclockwise (as viewed from the membrane domain of the enzyme) and that the rotation proceeds in 120° steps which were resolved subsequently into 90° and 30° substeps (or 80° and 40° substeps in other experiments). The ground-state structure probably represents the state of the enzyme at the end of the complete 120° rotary step. During ATP synthesis, the direction of rotation is reversed, and it is assumed that the order of the structural changes accompanying ATP hydrolysis is also reversed. One significant question that arises is how is the stepping action

generated from the turning of the rotor? The most likely explanation is that before a 120° step occurs energy is stored from the turning rotor by an elastic element, and then released in packet (or two subpackets corresponding to the substeps) in order to generate the stepping action. This elastic element is likely to reside in the α -helical coiled-coil region of the γ -subunit, but it remains possible that the peripheral stalk participates in transient energy storage also. However, the main role of peripheral stalk is probably to help the $\alpha_3\beta_3$ domain to resist the rotational torque of the rotor.

The main features of the rotary action of the F-ATPase and the synthesis of ATP are shown in [Movie 1](#).

Bioenergetic Cost of Making an ATP Molecule

Knowledge of the main architectural features of the F-ATPases and their functions allows a fundamental deduction to be made about energy transduction in the organisms in which these enzymes are found, namely the number of protons that are required to be translocated through the energy-transducing membrane for each ATP molecule that is synthesized by the F-ATPase from ADP and inorganic phosphate. This parameter is the bioenergetic cost to the organism of making each ATP molecule. Since each 360° rotation of the rotor of the F-ATPase produces three ATP molecules from the F₁ domain of the enzyme, and each 360° rotation of the c-ring requires the translocation of the same number of protons as there are c-subunits in the ring, the bioenergetic cost to the F-ATPase is the number of c-subunits in the c-ring divided by 3. The c₈-rings in the bovine enzyme are the smallest c-rings that have been observed hitherto, and it is likely that they occur in all vertebrate F-ATPases, and probably in the enzymes from invertebrates also. The associated bioenergetic cost to these F-ATPases is 2.7 protons/ATP. In other organisms where ring sizes of 9, 10, 11, 13, 14, and 15 have been observed, the bioenergetic cost to the F-ATPase will be 3.0, 3.3, 3.7, 4.3, and 5.0 protons/ATP, respectively. In mitochondria, ATP is produced in the matrix of the organelle, and it is made available as a source of cellular energy by exchanging it for external ADP. Inorganic phosphate is also actively transported back into the matrix of mitochondria. The combination of the electrogenic exchange of an internal ATP for an external ADP and the nonelectrogenic symport of phosphate and a proton adds one proton to the total required to provide ATP to the cellular cytoplasm, and so the cost to mitochondria containing an F-ATPase with a c₈-ring will be 3.7 protons. In mammalian mitochondria for each two electrons transferred to oxygen or succinate, 10 or 6 protons, respectively, are translocated out of the matrix. Therefore, the number of moles of ADP phosphorylated to ATP per two electrons transferred to oxygen, known as the P/O ratio, will be 10/3.7 and 6/3.7 or 2.7 and 1.6, respectively, for NADH and succinate, similar to the experimental values of 2.5 and 1.5. P/O ratios have been less studied in other species, and there is uncertainty about the proton stoichiometries of their electron transfer complexes. Nonetheless, similar considerations apply to their F-ATPases, except that in eubacteria there is no requirement to translocate ATP, and ADP and phosphate across the energy-transducing membrane.

Figure 3 The structure of the F_1 catalytic domain bovine F-ATPase in the ground state of the catalytic cycle. The subunits of the protein are depicted in ribbon representation. The α -, β -, γ -, δ -, and ϵ -subunits are red, yellow, blue, green, and purple, respectively. Top left, the complete F_1 domain with three α - and three β -subunits and single copies of γ -, δ -, and ϵ -subunits. In the intact F-ATPase, the rotor of the enzyme consists of the central stalk interacting via its foot with loop regions between the N- and C-terminal α -helices of the eight c-subunits in the F_0 membrane domain. In the top right, bottom left and right diagrams, the three different conformations of the catalytic β -subunits that are present in the structure in the top left panel are shown, together with the central stalk (γ -, δ -, and ϵ -subunits) and an α -subunit, for reference. Each β -subunit has three domains, the N-terminal domain (top) is made of β -sheets, the nucleotide-binding domain (middle) is a mixed α - β structure, and the C-terminal domain (bottom) is a bundle of six α -helices. Each of the three β -subunits has been obliged by the asymmetry of the α -helical coiled-coil region of the γ -subunit to adopt a different conformation, denoted β_{TP} , β_{DP} , and β_E , with different affinities for nucleotides, the β_{TP} - and β_{DP} -subunits can each bind either ADP or ATP, and the β_E -subunit is unable to bind any nucleotide. During the catalytic cycle of ATP synthesis or hydrolysis, the rotation of the central stalk takes each β -subunit through each of the three conformations. As the rotor turns, this action leads to the binding and entrapment of ADP and phosphate at the β_E -site as it closes, ATP formation at the β_{DP} -site, and ATP release from the β_{TP} site as it opens and converts back to the β_E site. Each 360° rotation of the central stalk (clockwise as viewed from beneath) leads to the formation of an ATP molecule from each of the three β -subunits.

Regulatory Mechanisms

Different types of F-ATPases have different mechanisms of inactivation and reactivation of ATP synthesis under conditions of low and increasing available energy. In mitochondria and chloroplasts, when the pmf is low, ADP-Mg (without inorganic phosphate) remains bound to one of the three catalytic sites of the enzyme (E) forming an inactive complex, E-ADP. In chloroplasts, it is thought that the inactive E-ADP state is stabilized during the hours of darkness by formation of an intramolecular disulfide linkage in the γ -subunit of the F-ATPase. When daylight is restored, the enzyme is reactivated by thioredoxin-regulated reduction of the disulfide and

energy-dependent dissociation of the ADP-Mg. The role of the bound ADP-Mg in the physiological regulation of the mitochondrial enzyme is less clear. At a pH of about 6.7 or below, the mitochondrial F-ATPase forms a 1:1 complex with an inhibitory protein, IF_1 . The formation of the inhibited complex requires the hydrolysis of two ATP molecules, and in the inhibited complex, the inhibitor is bound in a complex-binding site at a catalytic interface between the α_{DP} - and β_{DP} -subunits. The inhibition is relieved by restoration of an adequate membrane potential difference, allowing the enzyme to rotate the rotor in the synthetic direction, with the ejection of the inhibitor from its binding site and the resumption of the synthesis of ATP.

Despite similarities between the subunits of the F_1 domains of mitochondrial and eubacterial enzymes, for reasons that are not understood, mitochondrial IF_1 has no effect on eubacterial F-ATPases. However, the eubacterial F-ATPase from *Paracoccus denitrificans* and other α -proteobacteria have their own inhibitor protein, known as the ξ -subunit, that is thought to prevent ATP hydrolysis. However, the protein is not obviously closely unrelated to mitochondrial IF_1 , and its mode of action is not known. Other eubacterial F-ATPases, exemplified by the enzymes from *E. coli* and from the moderate thermophile, *Bacillus PS3*, appear to be able both to synthesize and to hydrolyze ATP, depending on whether they are operating under aerobic or anaerobic conditions. In addition, an inhibitory mechanism has been demonstrated *in vitro* for the enzymes from *E. coli* and *Bacillus PS3* involving the ϵ -subunit which is bound both to the γ -subunit in the central stalk of the F_1 -domain and to the c-ring in the membrane domain of the enzyme (see Figure 1). In a structure of the isolated ϵ -subunit, the N-terminal domain of the protein is folded into a 10-stranded β -sandwich, and the C-terminal region consists of two side-by-side α -helices. In the intact enzyme, the β -sandwich domain is involved in binding the subunit to the γ -subunit and the c-ring, and the α -helical C-terminal region has been proposed to adopt two different conformations, down and up. In the down conformation, the two α -helices are held associated closely with the β -sandwich by an ATP molecule bound (evidently without a magnesium ion) between the two domains. In the absence of bound ATP, the two α -helices are thought to assume the up position, where it has been proposed that they could interact with the $\alpha_3\beta_3$ complex and inhibit the enzyme in the ATP hydrolysis direction. However, the up position has not been captured in a high-resolution structure of the intact F_1 -domain, and a coherent explanation of the physiological context for such an inhibitory mechanism is lacking. Other eubacterial F-ATPases, exemplified by the enzymes from *Caldalkalibacillus thermarum* and *Mycobacterium tuberculosis*, synthesize ATP in the usual way under aerobic conditions, but they are not able to hydrolyze ATP under physiological conditions. Their latent ATP hydrolase activities can be activated only under nonphysiological conditions. Currently, there is no adequate molecular explanation for these observations.

Conclusions

The general structural and mechanistic molecular principles by which the F-ATPases from eubacteria, chloroplasts, and

mitochondria make ATP are now well established. However, it is apparent that the F-ATPases from these three sources differ substantially in the details of their operation, for example, in the amount of energy required to generate an ATP molecule, in the structures and possibly functions of their peripheral stalks, and in their modes of regulation. Thus, in order to gain a complete understanding of these enzymes, it will be necessary to establish separately the details of their operation in each class.

Glossary

AMP-activated kinase (AMPK) AMPK is phosphorylated (activated) by AMP-activated kinase when the AMP/ATP ratio increases. pAMPK phosphorylates and reduces acetyl-CoA carboxylase activity reducing fatty acid synthesis.

Enzyme-linked immunosorbent assay (ELISA) A commonly used immunological method to measure a target antigen in blood or any other biological sample. There are variations of the ELISA format but, generally, an antibody absorbed to a plastic well used to capture the antigen and a second antibody, which binds to a distinct epitope, is utilized as a detector. The detector antibody is often biotinylated to be visualized by an avidin-based colorimetric system.

Gleason grade A morphology-based grading system of prostate-cancer grading, based upon the growth pattern of the tumor, which is nearly universally applied to the clinical management of prostate cancer.

HER2/*neu* A proto-oncogene encoded by the ERBB2 gene; it has also been designated as CD340. Approximately,

15–20% of breast cancers amplify the HER2/*neu* gene or otherwise overexpress the protein. Patients whose breast cancers overexpress HER2/*neu* have a worse prognosis.

There is a relationship between HER2/*neu* and fatty acid synthase expression in human breast cancer.

Tumor heterogeneity When human cancers are studied with immunohistochemistry for biomarker expression, nearly any antigen will show varied amounts of expression in regions of the tumor and variation from cell to cell, which is defined as tumor heterogeneity.

Xenograft A cancer treatment model where human cancer cells are injected into an immunodeficient animal – usually athymic or severe combined immunodeficient (SCID) mouse. The cells are usually injected subcutaneously in the flank where growth and response to treatment can be measured with calipers. Orthotopic xenografts describe a model where the human cancer cells are injected into the same primary tissue in the mouse, that is, human lung cancer cells are injected into the trachea of mice, and human ovarian cancer cells are injected into mouse ovaries.

One of the most consistent biochemical changes associated with cancer is its reliance upon aerobic glycolysis described in the 1920s by Otto Warburg. Glucose metabolism continues to be exploited as a treatment strategy for cancer, based upon his discovery. More recently, cancer-related changes in fatty acid metabolism have provided an additional biochemical pathway replete with enzyme targets showing promise for both cancer diagnosis and therapy. Moreover, changes in fatty acid metabolism appear early during cancer development. Thus, these biochemical changes may play a role in promoting cellular transformation. In this article, fatty acid metabolism is reviewed as it relates to human cancer, highlighting fatty acid synthesis, acyl-CoA synthetase (ACS), and racemase. These have been selected because they represent targets for cancer diagnosis or treatment.

Overview of the Fatty Acid Synthesis Pathway

Within the last decade, most human cancers have been found to undergo high levels of *de novo* fatty acid synthesis compared to surrounding normal tissues. Enzymes in this pathway have become targets for both cancer therapy and diagnosis. At first, cancer cells undergoing high levels of fatty acid synthesis was a surprising and controversial concept, because our understanding of the role of fatty acid synthesis was borne out of studies in liver and other normal lipogenic organs.

In lipogenic organs, such as liver and adipose tissue, fatty acid

synthesis converts excess carbohydrate calories to fatty acids, which are ultimately stored as triglycerides. The triglyceride droplets in liver can grow to occupy a substantial mass of the hepatocyte, the so-called large droplet steatosis seen in fatty liver disease. In contrast, most cancer cells do not store appreciable amounts of fat as triglyceride. Renal cell carcinoma and liposarcomas are the only two human cancers with appreciable storage triglyceride, a feature used in their diagnosis. Although the basic biochemical pathway is present in both transformed and normal cells, fatty acid synthesis functions to store energy in the liver, while in cancer cells, it appears to maintain energy balance.

More than 20 enzymes contribute to the synthesis of fatty acids from glucose to palmitate. [Figure 1](#) outlines the pathway, highlighting the key enzymes of interest to oncology research. A brief summary of pathway function in lipogenic cells provides the background for its function in cancer. It is to be borne in mind, however, that in lipogenic tissues such as liver, this pathway is highly regulated by diet, whereas in the cancer cell, dietary regulation is minimal.

In the fed state, when energy is surfeit, glucose enters the mitochondria and exits as citrate to provide carbon for fatty acid synthesis. In the cytoplasm, citrate is converted to acetyl-CoA, a key substrate for fatty acid synthesis, by citrate lyase. Malonyl-CoA, the main substrate providing carbon for fatty acid synthase (FASN), is synthesized by acetyl-CoA carboxylase (ACC), in an adenosine triphosphate (ATP)-dependent reaction. ACC is the pace-setting enzyme of the fatty acid synthesis pathway. ACC activity is rapidly regulated by a number of substrates and hormones allowing the organism to adapt rapidly to

[†]Deceased.

Figure 1 Fatty acid synthesis pathway from glucose to palmitate. This pathway schematic highlights enzymes and substrates that are of interest to fatty acid metabolism and cancer. See text for details.

the energy demand. ACC activity is increased by citrate, insulin, and ATP, and is decreased by palmitoyl CoA, glucagon, and adenosine-monophosphate-activated protein kinase (AMPK), which phosphorylates ACC to inactivate it. During times of energy excess, citrate leads to an aggregation of ACC molecules, which provides a positive feedforward stimulation of ACC activity. When energy is in surplus, the decreased AMP/ATP ratio inactivates AMPK, preventing the phosphorylation and inactivation of ACC, and allowing fatty acid synthesis to proceed.

FASN is the enzyme responsible for the reductive synthesis of fatty acids from acetyl-CoA and malonyl-CoA. Its predominant (80%) product is the 16-carbon saturated free fatty acid, palmitate, which must be esterified to CoA prior to its conversion to triglyceride or its use in other lipid moieties. ACS esterifies free fatty acids to CoA whether derived from the diet or *de novo* synthesis. There is a family of ACS enzymes, which can esterify short- to very-long-chain fatty acids to CoA, which is discussed in more detail in another section. The final fate of most of the endogenously synthesized fatty acids in liver and adipose tissue is esterification to glycerol as storage triglycerides. In mammary gland fatty acid synthesis, there is a specialized thioesterase that cleaves the fatty acids from FASN to produce, predominantly, the 10-carbon free fatty acid, decanoate. Decanoate is present in human breast milk and is easier for the infant to digest than long-chain fatty acids such as palmitate.

As a consequence of a high-fat diet, vigorous exercise, prolonged fasting, or outright starvation, fatty acid synthesis, along with other forms of reductive synthesis, must be reduced to conserve energy. Rapid regulation of the pathway occurs through citrate and AMPK. As ingestion of carbohydrates is reduced, citrate efflux from the citric acid cycle to the cytoplasm declines, leading to decreased ACC activity. As the AMP/ATP ratio rises, AMPK is activated by phosphorylation. pAMPK, in turn, phosphorylates and inactivates ACC, further diminishing fatty acid synthesis. If starvation continues, FASN expression would be highly downregulated in the liver within 24 h.

Whereas the starvation state requires fatty acid synthesis to cease, it concomitantly entails an increase in fatty acid oxidation. The rapid regulation of fatty acid oxidation is conveniently provided by malonyl-CoA, the substrate of FASN. Malonyl-CoA, the product of ACC, plays an important role in

cellular energy regulation. In addition to acting as a substrate for FASN, malonyl-CoA regulates fatty acid oxidation through its allosteric inhibition of carnitine palmitoyl-transferase-1 (CPT-1), the rate-limiting transporter of long-chain fatty acids into the mitochondria for oxidation. Thus, when the fatty acid synthesis pathway is active, the high steady-state levels of malonyl-CoA inhibit CPT-1, preventing the futile cycle of oxidation of newly synthesized fatty acids. To further maintain physiological levels of malonyl-CoA, malonyl-CoA decarboxylase (MCD) catabolizes malonyl-CoA back to acetyl-CoA, preventing accumulation of malonate, which is toxic to cellular respiration.

The fatty acid synthesis pathway acts as a fulcrum between states of energy abundance and starvation. It is therefore plausible that it could act to maintain energy balance in the cancer cell with its dysregulated drive to replicate, survive, and metastasize.

FASN Function in Cancer

FASN is the most studied enzyme of this pathway in cancer cells. Cytoplasmic or mammalian type I FASN contains seven distinct enzyme activities on a single ~250-kDa polypeptide, which functions as a dimer producing two molecules of free palmitate. FASN is represented by a single gene without isoforms and catalyzes the nicotinamide adenine dinucleotide phosphate (NADPH)-dependent synthesis of palmitic acid, a 16-carbon saturated free fatty acid. One acetyl-CoA and seven malonyl-CoA contribute the carbon for palmitate synthesis. The basic structure and function of this enzyme do not appear to be altered in cancer cells; the specific activity of FASN purified from cancer cells is similar to that from nontransformed cells, and palmitic acid is its predominant product.

In normal subjects, FASN expression and activity are relatively restricted to organs without rapidly proliferating cellular compartments such as liver, adipose tissue, lactating mammary gland, and brain. The exception is the high levels of FASN expression in the endometrium during the proliferative phase. FASN is not expressed in skeletal, cardiac, or smooth muscle; only limited expression has been identified in other organs with more rapidly proliferating cellular compartments such as bone

marrow and gastrointestinal tract. The relative lack of expression in normal proliferating cellular compartments makes it an attractive target for cancer treatment.

FASN expression in human cancer

About 15 years ago (mid-1990s), high levels of FASN were reported in human breast cancer cells. Since then, high levels of FASN expression have been found in most human carcinomas, with expression also detected in sarcomas and some hematological malignancies, using a variety of techniques including immunohistochemistry and messenger RNA (mRNA) detection. Immunohistochemistry demonstrates cytoplasmic localization of FASN in human colon cancer as seen in [Figure 2](#). Not all primary cancers of a particular cancer subtype type express FASN, nor do all the cells in a particular tumor express the same amount of the enzyme which is characteristic of tumor heterogeneity. Comparing FASN expression in cancers to their biological behavior has shown a relationship between FASN expression and tumor virulence, which is discussed next.

The regulation responsible for the high levels of FASN expression in cancer is complex and incompletely understood. Cancer cells do not exhibit the dramatic dietary regulation of FASN expression as the liver. For example, at autopsy, FASN expression is often low to absent in the liver due to cachexia and inanition, but metastatic tumor deposits show abundant FASN expression by immunohistochemistry. In tumors whose growth is dependent upon androgens or estrogen/progesterone, such as breast or prostate cancer, FASN expression is largely driven by sex steroid hormones. In prostate cancer and human prostate cancer cell lines, FASN is positively regulated by androgens. In xenograft studies of human prostate cancer, high levels of FASN expression in the xenografts fell following castration. When the animals were treated with exogenous testosterone, FASN expression increased to precastration levels. In long-term castrated animals with relapsed androgen-independent tumors, FASN expression again increased. These data in xenografts were reflected in studies of human disease. Following therapeutic orchiectomy, tumor metastases shrink

and FASN expression is markedly reduced in the remaining prostate tissue consistent with androgen control of FASN expression in the prostate. However, when the tumor reappeared years later as androgen-independent disease, FASN expression was high in metastatic deposits studied at autopsy. Thus, it is likely that FASN expression in lethal prostate cancer, following androgen ablation, reappears under control of androgen-independent mechanisms.

In cancers whose growth is independent of sex steroid hormones, such as lung or colon cancer, the transcriptional regulation of FASN is less well understood. In these tumors, fatty acid synthesis is increased likely as a result of the actions of oncogenes. For example, phosphorylated (activated) Akt phosphorylates and activates ATP citrate lyase, which provides acetyl-CoA for fatty acid synthesis. In addition, pAkt through its inhibition of the tuberous sclerosis complex (TSC1/TSC2) and subsequent inhibition of Rheb, increases mammalian target of rapamycin (mTOR) activity. Activated mTOR increases glycolysis and protein synthesis. As a secondary consequence of increased flux through glycolysis, the pentose phosphate pathway provides ribose for nucleic acid synthesis and NADPH for enhanced fatty acid synthesis. Thus, the combination of pAKT and mTOR leads to a cascade of events including increased glycolysis (aerobic glycolysis), protein and fatty acid synthesis. Thus, FASN expression, in some instances, is increased because of a programmatic shift in cellular metabolism, as a result of Akt activation. Alternatively, in a study of human prostate cancer, fluorescence *in situ* hybridization identified a gene copy gain for FASN of 24% in all prostate cancers. In cases where FASN expression was increased as determined by immunohistochemistry, an increase in gene copy number occurred in 59% of the specimens. Thus, in addition to androgens, increased gene copy number may also contribute to increased FASN expression in prostate and other cancers.

FASN and cancer diagnostics

Although high levels of FASN expression occur commonly in human cancers, not all cancers have uniformly high levels of expression. FASN expression levels in breast, prostate, pancreas, and ovarian cancer tissues have been shown to have prognostic value, as increased expression was associated with more clinically virulent disease. In prostate cancer, high levels of FASN expression were associated with extension of cancer beyond the prostate and into the seminal vesicle, which indicates a high likelihood of systemic disease that is not yet clinically detectable. Others have found a relationship between FASN expression and prostate cancer high Gleason grade and disease progression.

FASN has also been detected in the blood of patients with breast, colon, prostate, ovarian, and pancreas cancer at levels 5–60-fold of those found in normal subjects using an enzyme-linked immunosorbent assay (ELISA). FASN in the blood originates from cancer cells as blood levels decline postresection of the cancer. The mechanism whereby FASN is elaborated from the cancer cell into the blood is unknown. FASN is not a secretory protein, as it does not contain the requisite signal peptide. Recently, however, cancer cells have been shown to shed exosomes, 40–100-nm-diameter nanovesicles of endocytic origin. Proteomic analysis of exosomes from human colon and bladder cancer has detected FASN sequences, which may

Figure 2 FASN expression in human colon cancer. Immunohistochemistry localizes FASN to the cancer cell cytoplasm (brown staining) in human colon cancer (magnification $\times 400$).

account for its presence in the serum. FASN has also been detected in bovine and human milk as part of the milk fat globule; this form of protein elaboration may occur in human breast cancers, which produce milk proteins. Alternatively, FASN may also be elaborated from apoptotic cancer cells and nonspecifically enter the circulation.

Thus, in the realm of cancer diagnosis, FASN expression in tissues may aid in the pathological diagnosis of cancer and assist in determining prognosis. The clinical utility of serum FASN determination is under active investigation. Serum FASN levels may prove to be helpful in monitoring cancer therapy or perhaps serve to aid in cancer detection in the population at large.

FASN as a therapeutic target

As it was believed that cancer cells have access to adequate amounts of fatty acid from the blood, the detection of robust FASN activity in cancer cells was surprising. As the pathway consumes ATP and large amounts of anabolic reducing equivalents, it must provide some vital function for cancer cells. Otherwise, FASN-negative clones would likely have both an energetic and a synthetic advantage over FASN-positive clones, leading ultimately to predominantly FASN-negative tumors. Indeed, quite the opposite is true; as cancers progress, they often express higher levels of FASN.

Thus, the combination of both basic biochemical and clinical observations led to studies of fatty acid synthesis inhibition in human cancer cells. With its seven distinct enzymes, FASN has been the focus of small-molecule pharmacological inhibition. Early studies of FASN inhibition employed a natural product, cerulenin, which inhibits both mammalian (type I) and prokaryotic (bacterial) type II FASN. Cerulenin forms a covalent adduct with the ketoacylsynthase domain of both type I FASN and type II KAS, acting as a suicide inhibitor with a low micromolar IC_{50} against purified FASN from human cancer cells. As might be predicted from FASN expression studies, most human cancer cell lines undergo brisk fatty acid synthesis in culture, even in the presence of 10% fetal calf serum, which provides sufficient fatty acid for cancer cell growth. Nonetheless, cerulenin was cytotoxic to human cancer cells *in vitro* with LC_{50} s in the low micromolar range for most cell lines. Many types of human cancer cells were susceptible to cerulenin-induced apoptosis including breast, prostate, colon, and ovarian cancer cell lines. In addition to cultured cells, cerulenin had activity *in vivo* against human cancer cell grown in athymic mice. However, the chemical instability and reactivity of cerulenin precluded its further clinical development.

C75 was the first synthetic small-molecule inhibitor of FASN. C75 was cytotoxic to many types of human cancer cell lines *in vitro* and showed significant antitumor activity against human cancer xenografts. However, substantial weight loss in the mice limited its utility, and it was found that the weight loss was due to C75 stimulation of CPT-1 activity leading to enhanced fatty acid oxidation. More recently, pharmacological inhibition of FASN has employed new chemical scaffolds and other enzyme targets on FASN. Thiolactomycin, another prokaryotic natural product FASN inhibitor, which occupies a site on the beta ketoacylsynthase distinct from cerulenin, has led to a wealth of new FASN inhibitors. Compounds targeted to the enoyl reductase domain on FASN have also afforded new

opportunities for synthetic chemistry. Drugs approved for other uses, such as orlistat, a pancreatic lipase inhibitor, have been shown to have anti-FASN activity as does triclosan, a type II FASN inhibitor used widely in personal care products. Although there is great variation in potency, these myriad of FASN inhibitors have shown activity *in vitro*, against human cancer cell lines derived from diverse primary sites. In addition to pharmacological inhibition, siRNA against FASN has been shown to be cytotoxic to human cancer cells *in vitro*.

A variety of pharmacological FASN inhibitors have shown activity *in vivo* against human cancer xenografts in athymic or SCID mice. There have been at least 12 reports of FASN inhibitors exhibiting antitumor activity against the following human cancer xenografts: breast, lung, prostate, colon, ovary, thyroid, malignant mesothelioma, and leukemia. In a study of mice bearing human non-small-cell carcinoma xenografts, oral treatment with a synthetic FASN inhibitor for 2 weeks led to substantial reduction in tumor growth. Similar results were obtained with orthotopic (lung) xenografts. These FASN inhibitors did not increase fatty acid oxidation and as such did not induce substantial weight loss. Signs of toxicity in the mice were not identified. FASN inhibition has led to the reduction of tumor growth of a number of diverse human cancer xenografts suggesting its utility as a target for cancer therapy.

In addition to established cancers, high levels of FASN expression have been found in a number of premalignant lesions in the breast, prostate, colon, and oropharynx. Using the prostate as an example, high FASN expression was found in prostatic intraepithelial neoplasia (PIN), thought to be a precursor lesion to invasive prostate cancer. Moreover, FASN expression has also been identified in histologically normal prostatic epithelium adjacent to invasive cancer, which may indicate a field effect of normal-appearing tissue at risk for development of cancer. Based on these and other observations, animal models of genetically induced cancer or chemical carcinogenesis have been treated with FASN inhibitors to prevent the development of neoplasia. FASN inhibitors substantially reduced mammary cancer development in transgenic HER2/*neu* mice. In this model, HER2/*neu*, known to upregulate FASN expression, was restricted to the mammary epithelium. FASN inhibition delayed the growth of transformed breast epithelium and led to complete abrogation of cancer growth in about 25% of the mice. The effects on the mice were limited to the mammary gland. In mice treated with chemical carcinogens to induce lung cancer, FASN inhibitors were administered orally twice a day for 4 months. These daily treatments led to a dramatic reduction of lung cancers in both urethane and NKK [4-(methylnitrosamino)-1-(3-pyridyl)-1- butanone] induced tumors. Interestingly, pAkt expression was reduced in the tumors of these FASN-inhibitor-treated animals compared to controls. In addition, lung cancer incidence was significantly reduced in rat models of chemical carcinogenesis. Thus, FASN inhibition is cytotoxic to established cancers and is able to prevent the development on cancers known to have high levels of FASN expression.

Mechanism of action of FASN inhibition

The *in vitro* and *in vivo* anticancer activity of FASN inhibition is well documented; however, the mechanism of action surrounding its cytotoxicity is under active investigation. What

survival advantage FASN expression and activity affords the cancer cell is poorly understood and likely differs depending on the primary site and morphological type of cancer. It has been postulated that reductive fatty acid synthesis helps the cancer cell maintain redox balance in the low oxygen tension found in human tumors by transferring electrons to fatty acids rather than oxygen. Indeed, FASN expression is upregulated by hypoxia, and FASN is highly expressed in hypoxic regions of tumors. Caveolin-1 (Cav-1) is a palmitoylated lipid raft protein that has been implicated in prostate cancer progression. Cav-1 and FASN have been shown to be coordinately regulated in prostate cancer and FASN may form a complex with Cav-1 based on co-immunoprecipitation. In Cav-1^{-/-}/TRAMP mice, FASN was not upregulated in the prostate tumors and the cancers were smaller and less virulent based upon a reduction in their ability to metastasize. Recent studies have found a relationship between high levels of FASN expression and reduced level of intrinsic apoptosis in human prostate cancer. In breast cancer, HER2/*neu* has been shown to be coordinately expressed with FASN, which may act together to support tumor growth.

Pharmacological studies have studied the mechanism of action responsible for the antitumor activity of FASN inhibition. There are a myriad of events that occur following FASN inhibition related to cell proliferation, survival, and apoptosis. Many of these effects occur hours following treatment. Within minutes of pharmacological FASN inhibition, there is an increase in the AMP/ATP ratio and reduction of cellular redox power. These changes in cellular bioenergetics lead to a rapid phosphorylation of AMPK, which attempts to reduce cellular proliferation and conserve energy. Although many of the changes of FASN inhibition in cancer cells are likely contextual to the cell type and its culture conditions, it appears that the FASN pathway functions to maintain energy balance in the cancer cell. Once the energy balance is disrupted, the dysregulation of cellular proliferation inherent to many types of cancer cells leads to eventual cell death.

If FASN inhibition triggers energy imbalance in the cancer cell, what is the trigger? Some clues have emerged from pharmacological studies of ACC inhibition. It has been found that 5-tetradecyloxy-2-furoic acid (TOFA) is a competitive inhibitor of ACC, which is used to block the synthesis of malonyl-CoA. TOFA is a potent inhibitor of the FASN pathway. If cancer cells are treated with concentrations of TOFA or an FASN inhibitor that lead to a similar amount of pathway inhibition, the FASN inhibitor is far more toxic than the ACC inhibitor. This suggests that the elevated concentration of malonyl-CoA following FASN inhibition may be involved in its cytotoxic effect. In patients with an absence or inactivating mutation of MCD, there are high levels of free malonate, which are toxic to cellular metabolism. These infants fail to thrive and suffer from fatal malonic aciduria, and seizures. Malonate is a potent inhibitor of succinyl-CoA dehydrogenase, a member of both the citric acid cycle and complex II of the electron transport chain. Thus, one hypothesis is that pharmacological FASN inhibition could lead to a rapid but transient elevation of malonyl-CoA that overwhelms the baseline activity of MCD. The resulting malonate toxicity could lead to ATP reduction and subsequent metabolic failure in the proliferating cancer cell. Based on this hypothesis, MCD has been suggested as another potential

anticancer target. Both siRNA and pharmacological inhibition of MCD have been shown to be cytotoxic to human breast cancer cells *in vitro*. Moreover, pharmacological MCD inhibition potentiates FASN inhibition in human breast cancer cells. Although the understanding of the biochemical mechanism is yet incomplete, there is increasing evidence that FASN inhibition has selective antitumor activity, which likely involves energy balance disruption in the cancer cell.

Acyl-CoA Synthetase

Fatty acids must be esterified to CoA for any further metabolism, which is the function of the ACS. In humans, the CS family contains 26 genes, which activate short-, medium-, long-, or very-long-chain fatty acids. Of the six-member very long chain ACS family, ACSVL3 is present at low levels in neurons, but cannot be detected in glia. Recently, however, human malignant gliomas have been found to express high levels of ACSVL3. Knockdown of ACSVL3 expression has been shown to decrease the growth of malignant glioma cells *in vitro* and in xenografts. This effect is likely mediated through modulation of Akt function. As ACSVL3 expression has not been detected in normal murine cells, it is hypothesized that it might represent another metabolic target for cancer therapy.

Recently, long-chain fatty acyl-CoA synthetase 4 (ACSL4) has been found to be highly expressed in subsets of breast cancer and in prostate cancer. ACSL4 expression is overexpressed in estrogen-receptor negative breast cancers. The inverse relationship between sex-steroid-hormone-receptor expression and ACSL4 was also found in prostate cancer, where androgen-receptor negative cancers had upregulated ACSL4 expression. The function of this isoform in cancer has not yet been determined, but sensitivity of cancer cells to inhibitors of ACS was increased threefold in cancer cells with low levels of ACSL4 expression.

A-Methylacyl-CoA Racemase

A-Methylacyl-CoA racemase (AMACR) functions in normal cells to enable oxidation of branched-chain fatty acids. AMACR catalyzes the chiral inversion of a variety of 2-methyl fatty acyl-CoAs and thereby regulates their entry into the peroxisomal or mitochondrial oxidation pathways. Interestingly, AMACR is involved in the metabolism of phytanic acid, a dietary branched-chained fatty acid associated with the development of prostate and other cancers. AMACR was identified as a gene highly upregulated in prostate cancer through analysis of microarray data sets. A large multi-institutional study demonstrated that AMACR helped distinguish benign from cancer prostate tissue with 97% sensitivity and 92% specificity. AMACR has become a mainstay of diagnostic pathology along with the basal cell marker p63, to aid in the identification of small foci of prostate cancer on needle biopsies. A recent study has shown that AMACR and FASN immunostaining was superior to AMACR alone to detect cancer in needle biopsies of the prostate. In addition, AMACR has been shown to be prognostic in prostate cancer, as low levels of expression are found in more-aggressive disease.

Glossary

Activation of fatty acids The conversion of fatty acids into thioesters with coenzyme A.

Peroxisome Subcellular organelle that is enclosed by a single membrane.

Unsaturated fatty acids Fatty acids that contain one or more double bonds.

β -Oxidation Degradation of fatty acyl-coenzyme A thioesters by the sequential removal of two carbon atoms at a time in the form of acetyl coenzyme A.

Cellular Uptake and Activation of Fatty Acids

The uptake of fatty acids by animal cells seems to be a facilitated process even though fatty acids can diffuse unassisted across biological membranes. A number of proteins of the cellular membrane are thought to be involved in this process. However, their specific functions in fatty acid uptake have not been elucidated. Once fatty acids have crossed the cellular membrane, they either diffuse or are transported to mitochondria, peroxisomes, and the endoplasmic reticulum where they are activated by esterification with coenzyme A (CoA). The transfer of fatty acids from the cellular membrane to sites of their activation may be facilitated by fatty-acid-binding proteins (FABPs), a group of low-molecular-weight (14–15 kDa) proteins that are present in the cytosol of various animal tissues. The function of FABP as an intracellular carrier of fatty acids has not been proved nor other suggested roles of this protein in the uptake and storage of fatty acids have been established.

The cellular uptake of fatty acids is tightly coupled to their intracellular esterification with CoA. Acyl-CoA synthetases catalyze the adenosine triphosphate (ATP)-dependent esterification of fatty acids and CoA to produce fatty acyl-CoA, AMP, and pyrophosphate. Long-chain-specific acyl-CoA synthetases are associated with the outer mitochondrial membrane and the membranes of the endoplasmic reticulum and peroxisomes. Acyl-CoA synthetases with a preference for medium-chain fatty acids are mostly located in the matrix of mitochondria while short-chain specific acyl-CoA synthetases are found in the mitochondrial matrix and/or in the cytosol depending on the organ of the animal.

Fatty Acid Oxidation in Mitochondria

In animal cells, fatty acids are degraded both in mitochondria and peroxisomes, whereas in lower eukaryotes fatty acid oxidation is generally confined to peroxisomes. Acetyl-CoA formed by mitochondrial fatty acid oxidation is further oxidized to release energy that drives the formation of ATP by oxidative phosphorylation. In liver, acetyl-CoA is also utilized for the synthesis of ketone bodies.

Mitochondrial Uptake of Fatty Acids

Fatty acids are activated by their conversion to fatty acyl-CoA thioesters at the outer mitochondrial membrane while their degradation by β -oxidation takes place in the mitochondrial matrix. Because acyl-CoAs cannot efficiently cross the inner mitochondrial membrane, an uptake system exists that shuttles fatty acyl residues across the inner membrane. As illustrated in [Figure 1](#), the acyl residue of fatty acyl-CoA is transferred from CoA to carnitine at the outer mitochondrial membrane catalyzed by carnitine palmitoyltransferase I (CPT I). The resultant fatty acylcarnitine can cross the inner mitochondrial membrane in exchange for carnitine. This exchange is catalyzed by carnitine:acylcarnitine translocase (T). Once fatty acylcarnitine is in the mitochondrial matrix, it is converted back to fatty acyl-CoA by carnitine palmitoyltransferase II (CPT II), which is associated with the inner mitochondrial membrane. Medium-chain and short-chain fatty acids are not activated in the cytosol but directly enter the mitochondrial matrix where they are converted to their acyl-CoAs by medium-chain and short-chain acyl-CoA synthetases, respectively.

β -Oxidation in Mitochondria

Fatty acyl-CoAs in the mitochondrial matrix are substrates of β -oxidation. This cyclic process consists of four reactions that shorten the acyl chain of fatty acyl-CoA by two carbon atoms at a time and produce acetyl-CoA. As shown in [Figure 2](#), reaction 1a, β -oxidation begins with the removal of two hydrogens from carbon atoms 2 (α -carbon) and 3 (β -carbon) of acyl-CoA to form the corresponding 2-*trans*-enoyl-CoA. The hydrogens are initially accepted by the flavine adenine dinucleotide (FAD) cofactor of acyl-CoA dehydrogenase, the enzyme that catalyzes this reaction, then are transferred to the FAD of a soluble matrix enzyme named electron transferring flavoprotein, and finally are fed into the mitochondrial electron transport chain, which supplies the energy for ATP formation by oxidative phosphorylation. In the second β -oxidation reaction, water is added across the double bond of 2-*trans*-enoyl-CoA by enoyl-CoA hydratase to yield

Figure 1 Carnitine-dependent transfer of fatty acyl groups across the inner mitochondrial membrane. ACS, acyl-CoA synthetase; CPT I and CPT II, carnitine palmitoyltransferase I and II, respectively; T, carnitine:acylcarnitine translocase.

Figure 2 β -Oxidation of fatty acyl-CoA. Reactions 1a, 1b, 2, 3, and 4 are catalyzed by acyl-CoA dehydrogenase, acyl-CoA oxidase, enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, and 3-ketoacyl-CoA thiolase, respectively. Abbreviations: FAD, oxidized form of flavine adenine dinucleotide; FADH_2 , reduced form of flavine adenine dinucleotide; NAD^+ , nicotinamide adenine dinucleotide.

L-3-hydroxyacyl-CoA (see **Figure 2**, reaction 2). The third reaction is the nicotinamide adenine dinucleotide (NAD^+)-dependent dehydrogenation of L-3-hydroxyacyl-CoA catalyzed by L-3-hydroxyacyl-CoA dehydrogenase (see **Figure 2**, reaction 3). The product of this reaction, 3-ketoacyl-CoA, is the substrate of the fourth and last reaction of β -oxidation catalyzed by 3-ketoacyl-CoA thiolase, which cleaves the compound in the presence of CoA between carbons 2 and 3 to yield an acyl-CoA shortened by two carbon atoms and acetyl-CoA (see **Figure 2**, reaction 4). Repetitive cycles of β -oxidation result in the complete degradation of fatty acids to acetyl-CoA and also propionyl-CoA, if fatty acids with an odd-numbered number of carbon atoms are involved.

Two or more enzymes with different acyl chain length specificities participate in each of the four reactions. Four acyl-CoA dehydrogenases are required for the β -oxidation of fatty acids. Their names, very long chain acyl-CoA dehydrogenase, long-chain acyl-CoA dehydrogenase, medium-chain acyl-CoA dehydrogenase, and short-chain acyl-CoA dehydrogenase, reflect their preferences for substrates of different acyl chain lengths. Together they efficiently dehydrogenate all acyl-CoAs that are formed during the β -oxidation of most dietary fatty acids. Two enzymes, one with a preference for short-chain and medium-chain substrates and another most active with long-chain substrates, cooperate in each of the three other reactions to metabolize a range of β -oxidation intermediates of different acyl chain lengths.

β -Oxidation of Unsaturated Fatty Acids

Unsaturated and polyunsaturated fatty acids also are degraded by β -oxidation. However, additional reactions are required to metabolize pre-existing double bonds that would otherwise interfere with the complete β -oxidation of unsaturated fatty acids. All double bonds found in unsaturated fatty acids can be classified as either odd- or even-numbered double bonds. Both classes are present in linoleic acid, which contains an odd-numbered double bond at position 9 and an even-numbered double bond at position 12 (see **Figure 3**). The degradation of linoleic acid therefore illustrates the β -oxidation of all unsaturated fatty acids. As outlined in the figure, linoleoyl-CoA (I; all Roman numerals refer to compounds), after passing 3 times through the β -oxidation cycle, yields 3-*cis*,6-*cis*-dodecadienoyl-CoA (II). This metabolite cannot enter another cycle of β -oxidation due to interference by the double bond at position 3.

Figure 3 Pathway for the β -oxidation of linoleoyl-CoA.

However, an additional (auxiliary) enzyme, Δ^3, Δ^2 -enoyl-CoA isomerase (enoyl-CoA isomerase), converts 3-*cis*,6-*cis*-dodecadienoyl-CoA (II) to 2-*trans*,6-*cis*-dodecadienoyl-CoA (III) that can complete its pass through one cycle of β -oxidation to yield 4-*cis*-decenoyl-CoA (IV). 4-*cis*-Decenoyl-CoA is dehydrogenated by acyl-CoA dehydrogenase to 2-*trans*,4-*cis*-decadienoyl-CoA (V), which is not a substrate of β -oxidation but which is reduced by nicotinamide adenine dinucleotide phosphate (NADPH) in the presence of 2,4-dienoyl-CoA reductase, the second auxiliary enzyme, to 3-*trans*-decenoyl-CoA (VI). The latter compound is converted by enoyl-CoA isomerase to 2-*trans*-decenoyl-CoA (VII) that can be completely degraded by β -oxidation. A third auxiliary enzyme, $\Delta^{3,5}, \Delta^{2,4}$ -dienoyl-CoA isomerase (dienoyl-CoA isomerase), catalyzes the isomerization of 3,5-dienoyl-CoA to 2,4-dienoyl-CoA. This reaction facilitates the complete β -oxidation of 3,5-dienoyl-CoAs that are minor metabolites of unsaturated fatty acids with odd-numbered double bonds.

Regulation of Mitochondrial Fatty Acid Oxidation

The rate of fatty acid oxidation changes in response to the nutritional and hormonal state of the animal. The rate of

fatty acid oxidation is high during fasting but low in the fed animal. One cause for this change is the higher concentration of unesterified (free) fatty acids in the circulation of the fasting animal as compared to the concentration in the fed animal. An increased concentration of free fatty acids results in higher rates of cellular uptake and oxidation of fatty acids. In liver, which has high capacities for both synthesizing and oxidizing fatty acids, a reciprocal relationship exists between these two processes. After feeding, when carbohydrates are converted to triacylglycerols, the rate of fatty acid synthesis is high because acetyl-CoA carboxylase is active. This enzyme catalyzes the carboxylation of acetyl-CoA to malonyl-CoA, the first committed intermediate in fatty acid synthesis. Malonyl-CoA binds to and effectively inhibits CPT I that initiates the uptake of fatty acids by mitochondria. Thus, when fatty acids are rapidly synthesized, the cytosolic concentration of malonyl-CoA is high and the mitochondrial uptake and oxidation of fatty acids are inhibited. This situation is reversed during fasting when lower blood glucose levels cause the plasma concentration of the hormone glucagon to increase and that of insulin to decrease. Glucagon promotes the phosphorylation and inactivation of acetyl-CoA carboxylase with the result that the cytosolic concentration of malonyl-CoA declines. The lower concentration of malonyl-CoA causes fatty acid synthesis to decrease and fatty acid oxidation to increase. The same regulatory mechanism may be effective in tissues such as heart and skeletal muscle that oxidize fatty acids but do not synthesize them. Although malonyl-CoA is generated in these tissues by acetyl-CoA carboxylase, it seems to be metabolized by decarboxylation catalyzed by malonyl-CoA decarboxylase.

Fatty Acid Oxidation in Peroxisomes

Peroxisomes of animal cells contain a β -oxidation system that partially degrades fatty acids in contrast to mitochondria that break down fatty acids completely. The enzymes of peroxisomal and mitochondrial β -oxidation are not the same. Different genes encode most of the peroxisomal and mitochondrial enzymes. Substrates of peroxisomal β -oxidation are the CoA derivatives of fatty acids and carboxylic acids that are poorly or not at all taken up by mitochondria as, for example, very long chain fatty acids, methyl-branched carboxylic acids (e.g., pristanic acid), prostaglandins, dicarboxylic acids, xenobiotic compounds (e.g., phenyl fatty acids), and hydroxylated cholestanoic acids that are precursors of cholic acid. However, peroxisomes of lower eukaryotes catalyze the complete β -oxidation of fatty acids, whereas mitochondria in the same organisms generally are devoid of a functional β -oxidation system.

The uptake and activation of fatty acids by peroxisomes remain poorly understood. While some fatty acids such as very long chain fatty acids may be activated by conversion to CoA esters in the peroxisomal matrix after directly entering animal peroxisomes, other fatty acids or carboxylic acids seem to be activated outside of peroxisomes. The uptake of fatty acyl-CoAs by peroxisomes is suspected to take place but has not been demonstrated. Carnitine does not seem to be required for this uptake.

The four reactions of β -oxidation in peroxisomes are similar to the corresponding mitochondrial reactions (see Figure 2). An exception is the first reaction, in which fatty acyl-CoA is dehydrogenated to 2-*trans*-enoyl-CoA by acyl-CoA oxidase while oxygen is reduced to H_2O_2 (see Figure 2, reaction 1b). The latter product is converted to H_2O and O_2 by catalase that is present in peroxisomes. At least two acyl-CoA oxidases exist in animal peroxisomes; one named palmitoyl-CoA oxidase is active with long-chain and medium-chain, but not short-chain acyl-CoAs that have straight acyl chains while the second acyl-CoA oxidase also acts on branched-chain acyl-CoAs. Since the acyl-CoA oxidase activity of lower eukaryotes extends over the whole spectrum of acyl-CoAs of various chain lengths, peroxisomes in these organisms, in contrast to those in animals, can degrade fatty acids completely. The second and third reactions of peroxisomal β -oxidation are catalyzed by enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase, respectively, that are associated with a same polypeptide. Two such multifunctional enzymes, MFE 1 and MFE 2, are present in animal peroxisomes. They differ from each other in that the 3-hydroxyacyl-CoA intermediate formed and acted upon by MFE 1 has the L configuration, whereas the intermediate of MFE 2 is the D isomer. Peroxisomes of yeast and fungi only contain the type 2 multifunctional enzymes. Two types of 3-ketoacyl-CoA thiolases are present in rat peroxisomes. One of the thiolases, referred to as SCP_x -thiolase, is unusual because it is part of a bifunctional protein that additionally contains a lipid-binding segment named sterol carrier protein (SCP). Studies with β -oxidation mutants have led to the conclusion that the partial β -oxidation of straight-chain fatty acyl-CoAs, like very long chain fatty acyl-CoAs, in animal peroxisomes requires palmitoyl-CoA oxidase, MFE 2, and 3-ketoacyl-CoA thiolase, whereas the partial degradation of branched-chain acyl-CoAs, such as pristanoyl-CoA, involves branched-chain acyl-CoA oxidase, MFE 2, and SCP_x -thiolase. Unsaturated and polyunsaturated fatty acids also are partially degraded in peroxisomes. The necessary additional enzymes, enoyl-CoA isomerase, 2,4-dienoyl-CoA reductase, and even dienoyl-CoA isomerase, are present in this organelle. The products of peroxisomal β -oxidation are chain-shortened acyl-CoAs, NADH, and acetyl-CoA. In addition, propionyl-CoA is formed when methyl-branched-chain substrates are degraded. Acyl-CoAs may be converted to the corresponding acylcarnitines before they exit from peroxisomes. The necessary carnitine acyltransferases active with medium-chain and short-chain acyl-CoAs have been identified in peroxisomes. However, little is known about transporters that facilitate the efflux of products from peroxisomes.

α -Oxidation and ω -Oxidation

α -Oxidation is the process that results in the oxidative removal of the first carbon atom, the carboxyl group, of a fatty acid or carboxylic acid to yield CO_2 and a fatty acid or carboxylic acid shortened by one carbon atom. In animals, this process occurs in peroxisomes where, for example, phytanic acid, which is derived from phytol of chlorophyll and which cannot be degraded by β -oxidation, is chain-shortened by one carbon atom to pristanic acid that can be degraded by β -oxidation. ω -Oxidation is the process by which fatty acids are oxidized at their terminal (ω) or penultimate ($\omega - 1$) carbon atom to form dicarboxylic acids. This process occurs at the endoplasmic reticulum and requires molecular oxygen. When β -oxidation of fatty acids is impaired, more fatty acids are converted to dicarboxylic acids by ω -oxidation.

Glossary

CHORE Carbohydrate response element, a DNA sequence that binds a unique carbohydrate response protein whose DNA-binding and transactivation activities are upregulated by glucose ingestion.

HUFA Highly unsaturated omega-6 and -3 fatty acids that uniquely regulate gene expression, cell differentiation, and are required for cognition and neural function.

LXR (liver-X receptor) A nuclear transcription factor that is activated by the binding of oxysterols and stimulated by the transcription of lipogenic genes.

SREBP-1 Sterol regulatory element binding protein-1, required for the transcription of genes encoding proteins of fatty acid biosynthesis.

De Novo Fatty Acid Biosynthesis of Saturated Fatty Acids

Saturated fatty acids are categorized as short (C2–C6), medium (C8–C12), long (C14–C18), and very long (C20–C24) fatty acids. Short-chain fatty acids are derived largely from bacterial fermentation such as that which occurs in the gut or rumen. Medium-chain fatty acids are characteristic of milk fat and are absorbed from the intestine directly into the portal blood, and subsequently metabolized largely by the liver. Fatty acids containing 14 or more carbons are absorbed from the intestine and transported to the periphery as chylomicrons. Very long chain fatty acids are largely found in neural tissue and used for myelin formation. The liver and adipose tissue of humans are the primary sites of conversion of excess carbohydrate to fatty acids, but fatty acid synthesis is more than just for conserving excess glucose as fat. Fatty acid synthesis is essential for cell membrane production, lung surfactant function, milk fat production, brain myelination, and fat storage. Consequently, nearly all tissues have the capacity to synthesize fatty acids.

De novo fatty acid biosynthesis in humans occurs in cytosol. Two enzymes, acetyl-coenzyme A (CoA) carboxylase and fatty acid synthase, are required for this process. The first and rate-limiting step is the conversion of acetyl-CoA to malonyl-CoA by acetyl-CoA carboxylase (bold letters show the carbon unit in malonyl-CoA that is derived from acetyl-CoA):

Fatty acid synthase catalyzes all of the subsequent steps for the synthesis of long-chain saturated fatty acids. Fatty acid synthase is made of a single peptide chain that possesses seven distinct catalytic domains. Fatty acid synthase first adds two carbons to acetyl-CoA using malonyl-CoA. Nicotinamide adenine dinucleotide phosphate (NADPH) is used as a reducing power in this reaction:

Fatty acid synthase repeats the acyl chain elongation, two carbons at a time, using malonyl-CoA as a substrate (bold letters show the carbon unit that is newly added from malonyl-CoA to the elongating carbon chain after one cycle of reaction):

When the carbon chain reaches 16, the thioesterase domain of fatty acid synthase releases free palmitate, completing fatty acid biosynthesis:

Regulation of Pyruvate Dehydrogenase in Mitochondria

Malonyl-CoA is the substrate used by fatty acid synthase to assemble the acetate units into fatty acids. The first step in malonyl-CoA production involves the mitochondrial formation of acetyl-CoA by pyruvate dehydrogenase's decarboxylation of pyruvate. This is followed by the intra-mitochondrial synthesis of citrate from acetyl-CoA and oxaloacetate. Citrate is transported from the mitochondria to the cytosol where it is cleaved by citrate lyase to cytosolic acetyl-CoA and oxaloacetate. The acetyl-CoA is available for carboxylation to malonyl-CoA by the biotin-containing enzyme acetyl-CoA carboxylase. The liver and adipose tissue of humans are the primary sites of conversion of excess carbohydrate to fatty acids. The source of hepatic or adipose pyruvate for fatty acid biosynthesis may be derived from the metabolism of glucose via the glycolytic pathway with the liver or adipocyte itself, or it may be provided to the liver and/or adipose tissues as lactate or alanine that is produced by glucose metabolism in peripheral tissues, such as the small intestine and muscle. Entry of pyruvate into the tricarboxylic acid (TCA) pathway of the mitochondria is determined by the activity of pyruvate dehydrogenase. The concentration of pyruvate dehydrogenase does not widely fluctuate,

but its catalytic activity is suppressed by phosphorylation and enhanced by dephosphorylation of the enzyme. Insulin and glucose stimulate dephosphorylation while glucagon and fatty acids enhance the phosphorylation. Thus, pyruvate entry into the TCA cycle is highly dependent upon the macronutrient composition of the diet, and the ratio of insulin to glucagon.

Malonyl-CoA and Fatty Acid Metabolism

Malonyl-CoA plays a pivotal role in energy metabolism. As the substrate for fatty acid synthase, the cytosolic concentration of malonyl-CoA determines maximum rates of *de novo* fatty acid synthesis. As an inhibitor of carnitine palmitoyltransferase, malonyl-CoA controls the rate of fatty acid entry into the mitochondria, and hence is a key determinant of the rate of fatty acid oxidation. Thus, conditions that lead to high levels of malonyl-CoA (e.g., high carbohydrate intakes) suppress fatty acid entry into the mitochondria and increase their flux to triglycerides. On the other hand, conditions that result in low cellular concentrations of malonyl-CoA favor fatty acid oxidation because the inhibition of carnitine palmitoyltransferase is released. The synthesis of malonyl-CoA is catalyzed by the biotin-containing enzyme, acetyl-CoA carboxylase. Acetyl-CoA carboxylase exists as two isoforms: a liver or type I and a muscle or type II. The two isoforms are distributed in the cell in a manner that results in an intracellular compartmentalization of malonyl-CoA (i.e., malonyl-CoA produced by acetyl-CoA carboxylase type I is the substrate for fatty acid synthase, while malonyl-CoA generated by the type II enzyme governs fatty acid entry into the mitochondria via regulation of carnitine palmitoyltransferase). Like pyruvate dehydrogenase, the catalytic activity, and hence the production of malonyl-CoA, by both acetyl-CoA carboxylase isoforms is regulated by phosphorylation and dephosphorylation of the protein. Acetyl-CoA carboxylase I and II are substrates for AMP-activated protein kinase (AMPK) and cyclic AMP-dependent protein kinase (PKA). AMPK activity is enhanced by leptin and adiponectin, two hormones that stimulate fatty acid oxidation and inhibit fatty acid biosynthesis. The dephosphorylation of acetyl-CoA carboxylase is carried out by protein phosphatase 1 and 2, and phosphatase activity appears to be stimulated under conditions where glucose flux through glycolysis is high. In addition to its rate of production by acetyl-CoA carboxylase, the concentration of malonyl-CoA is also dependent upon its rate of decarboxylation by malonyl-CoA decarboxylase. Malonyl-CoA decarboxylase is also a substrate for AMPK, and its phosphorylation leads to an increase in decarboxylation activity and a loss of malonyl-CoA. Thus, AMPK activation governs fatty acid partitioning between triglyceride synthesis and oxidation by coordinately inhibiting malonyl-CoA synthesis and stimulating its degradation. In addition to having its activity acutely regulated via phosphorylation and dephosphorylation, the amount of hepatic acetyl-CoA carboxylase, like other lipogenic enzymes, increases and decreases in concentration depending upon nutritional conditions, dietary composition, and hormonal milieu. For example, the hepatic abundance of acetyl-CoA carboxylase is low during fasting and diabetes, but is greatly induced by refeeding glucose or administering insulin. On the other hand, muscle type II acetyl-CoA carboxylase is not an adaptive enzyme. Thus, its production of malonyl-CoA

is solely dependent upon the phosphorylation state of acetyl-CoA carboxylase type II. In addition to playing a key role in the partitioning of fatty acids between storage and oxidation, malonyl-CoA may also be a central metabolite in appetite regulation. Thus, even though net fatty acid synthesis by humans is relatively small, the fatty acid biosynthetic pathway plays an instrumental role in human lipid metabolism. Since excessive cellular triglyceride production and accumulation is causatively linked to the development of insulin resistance and type II diabetes, factors regulating the fatty acid biosynthetic pathway will also exert a direct influence on the development of diabetes.

Nutritional Regulation of Lipogenic Gene Expression

Hepatic and adipose fatty acid biosynthesis is increased by the ingestion of a high carbohydrate diet and decreased by the consumption of a high-fat diet. Dietary regulation of lipogenesis is not simply a product of nutritional manipulation of hormonal balance. Rather, nutrients exert a specific influence on the expression of glycolytic and lipogenic proteins. Nutrients exercise their influence by modulating gene transcription, messenger RNA (mRNA) processing, mRNA decay, and by stimulating posttranslational protein modifications.

Carbohydrate Induction of Lipogenic Gene Transcription

Work over the past decade has identified a collection of transcription factors that are specifically targeted by glucose and fatty acids. Dietary carbohydrate induces lipogenic gene transcription in two ways. First, glucose increases the nuclear concentration of the potent lipogenic transcription factor SREBP-1. SREBPs are a family of transcription factors that were first isolated as a result of their properties for binding to the sterol regulatory element of genes encoding proteins of sterol metabolism. SREBP-2 is a regulator of genes encoding proteins of cholesterol metabolism. SREBP-1 exists in two forms, 1a and 1c. SREBP-1a is the dominant form in cell lines and is a regulator of genes encoding proteins involved in fatty acid biosynthesis as well as cholesterolgenesis. SREBP-1c constitutes 90% of the SREBP-1 found *in vivo* and is a determinant of lipogenic gene transcription. SREBP-1 is synthesized as a 125-kDa precursor protein that is anchored in the endoplasmic reticulum membrane. Proteolytic release of the 68-kDa mature SREBP-1 occurs in the Golgi system, and movement of SREBP-1 from the endoplasmic reticulum to the Golgi requires the trafficking protein SREBP cleavage-activating protein. Once released, mature SREBP-1 translocates to the nucleus and binds to the classic sterol response element and/or to a palindrome CATG sequence.

Glucose increases the abundance of precursor SREBP-1 by inducing SREBP-1 gene transcription. In addition, glucose elevates the nuclear concentration of SREBP-1 by stimulating the proteolytic release of mature SREBP-1 from its membrane-anchored precursor. These glucose effects are largely mediated by insulin although the signaling pathway involved is yet to be fully elucidated. Activation of phosphatidylinositol 3-kinase and protein kinase C λ (PKC λ) by insulin is required for both transcriptional induction and proteolytic activation of SREBP-1c.

A regulatory protein Insig2a is expressed in liver, and retains precursor SREBP-1 in endoplasmic reticulum, thus preventing SREBP-1 from proteolytic activation. Insulin stimulates proteolytic activation of SREBP-1 by degrading Insig2a mRNA.

A second effect of glucose is to stimulate the DNA-binding activity of select transcription factors involved with the transcription of lipogenic genes, notably a unique carbohydrate response factor (CHORE). Glucose exerts its effect by elevating the cellular concentration of the pentose shunt metabolite xylulose-5-phosphate. Xylulose-5-phosphate is a positive metabolite effector of phosphatase 2A, and increased phosphatase activity leads to the dephosphorylation of CHORE, increased translocation of CHORE from the cytosol to the nucleus, and a subsequent increase in its DNA binding to a specific carbohydrate response element (CHORE) in select glycolytic (e.g., pyruvate kinase) and lipogenic (e.g., fatty acid synthase) genes. The consequence is an increase in gene transcription followed by a rise in the abundance of glycolytic and lipogenic enzymes.

Suppression of Lipogenic Gene Expression by Omega-6 and -3 Fatty Acids

Glucose stimulation of lipogenesis is a nice example of a feed-forward regulatory mechanism that functions to enhance glucose storage as fatty acids. Interestingly, the saturated fatty acid products of the *de novo* fatty acid synthetic pathway do not feed back and suppress glycolytic and lipogenic gene expression or activity. Only omega-6 and -3 fatty acids (e.g., linoleic (C18:2n-6) and α -linolenic (C18:3n-3)) interfere with glycolytic and lipogenic gene expression (Figure 1). Highly unsaturated 20- and 22-carbon omega-6 and -3 fatty acids (HUFAs) inhibit glycolytic and lipogenic gene transcription through two different types of DNA regulatory response regions (HUFA-RR). One type

overlaps with the insulin response element (HUFA-RR/IRE), while the second region co-localizes with the carbohydrate response element (HUFA-RR/CHORE).

Co-localization of the HUFA-response region with the insulin response element

The HUFA-RR/IRE contains recognition sequences for SREBP-1c, NF-Y, Sp1, and USF. HUFAs inhibit the activity of promoters containing the HUFA-RR/IRE by decreasing SREBP-1c and NF-Y interactions with their respective recognition sequences. HUFAs lower the concentration of SREBP-1 precursor protein as well as inhibit the proteolytic release and nuclear localization of mature SREBP-1. In addition to inhibiting the proteolytic release of SREBP-1, HUFAs reduce the cellular content of precursor SREBP-1 protein by reducing the cellular abundance of SREBP-1 mRNA. HUFAs decrease the hepatic abundance of SREBP-1 mRNA, and consequently the hepatic content of precursor SREBP-1 protein, by accelerating SREBP-1 mRNA decay and by suppressing SREBP-1 gene transcription. The mechanisms by which HUFAs accelerate SREBP-1 mRNA decay remain unclear, but the mechanisms by which HUFAs suppress SREBP-1 gene transcription are beginning to emerge. The SREBP-1 gene contains two response elements for the lipogenic transcription factor liver-X receptor (LXR). Oxysterol ligand activation of LXR induces the transcription of SREBP-1. HUFAs reportedly displace oxysterol from LXR and, in this way, antagonize the transactivation activity of LXR. In addition, HUFA may stimulate the trapping of LXR as a PPAR α /LXR heterodimer. Thus, when the ratio of HUFA to oxysterol is low LXR/RXR heterodimers favor lipogenic gene expression, but when the ratio of HUFA to oxysterol is high the PPAR α /LXR and PPAR α /RXR heterodimer mixtures are poised toward a gene profile that favors fatty acid oxidation over fatty acid synthesis. Although SREBP-1 metabolism is highly responsive to HUFA,

Figure 1 Regulation of hepatic gene expression and lipid metabolism by HUFAs. ACC, acetyl-CoA carboxylase; AMPK, AMP-activated protein kinase; AOX, acyl-CoA oxidase; CPT, carnitine palmitoyltransferase; FA, fatty acid; FAS, fatty acid synthase; HUFAs, highly unsaturated fatty acids; PL, phospholipid; SMase, sphingomyelinase; TG, triglyceride; VLDL, very low density lipoproteins; $\Delta 5$ ase, Δ -5 desaturase; $\Delta 6$ ase, Δ -6 desaturase.

it is only one of several transcription factors targeted by HUFA. In fact, >50% of the HUFA control of fatty acid synthase gene transcription can be attributed to the NF-Y site at -99/-93. NF-Y is an abundant heterotrimeric nuclear protein that interacts with histone acetyltransferases, and consequently plays a role in modifying histone structure. HUFAs do not reduce the nuclear abundance of NF-Y but rather suppress NF-Y transactivation activity by decreasing its DNA-binding activity.

A CHO-response element within an HUFA-response region

Part of the HUFA-RR of certain lipogenic genes, notably fatty acid synthase, contains DNA-binding sites for several transcription factors (e.g., CHORF and HNF-4). The DNA-binding activities of CHORF and HNF-4 are dependent upon their state of phosphorylation. Phosphorylation of CHORF inhibits its binding to the CHORE and prevents HNF4 from forming the homodimers required for its DNA binding. AMPK phosphorylation of HNF4 also accelerates the decay of HNF4 protein. HUFA suppression of lipogenic gene transcription involves an inhibition of the translocation of CHORF from the cytosol to the nucleus. However, whether or not HUFAs exert their effects via AMPK activation remains equivocal; but HUFAs' ability to coordinately suppress lipogenesis and stimulate fatty acid oxidation is consistent with the established role that AMPK plays in the partitioning of fatty acids between triglyceride storage and fatty acid oxidation.

Unsaturated Fatty Acid Synthesis

Oleic and Palmitoleic Acid Synthesis

Palmitate (C16:0) and stearate (C18:0) are rapidly desaturated to mono-unsaturated palmitoleic (C16:1) and oleic (C18:1) acids by the stearoyl-CoA desaturase (also known as Δ -9 desaturase) system (Figure 2). Stearoyl-CoA desaturase exists in multiple isoforms that are derived from separate genes. The dominant form within a cell depends upon the origin of the cell. Stearoyl-CoA desaturase inserts a double bond between carbons 9 and 10. This desaturation reaction requires three different components: the desaturase itself, cytochrome *b5*, and cytochrome *b5* reductase. Oleic acid synthesis is required for a variety of reasons. In particular, it appears to be required for the hepatic secretion of very low density lipoproteins.

Arachidonic and Docosahexaenoic Acid Synthesis

While oleic acid clearly plays an important role in overall energy metabolism, it cannot fulfill the biological requirements for growth, reproduction, cell signaling, and cell differentiation. These requirements can only be fulfilled by long-chain fatty acids from the omega-6 and -3 fatty acid family, that is, linoleic (C18:2n-6) and α -linolenic (C18:3n-3), respectively (Figure 2). Linoleate and α -linolenate undergo desaturation and elongation to 20- and 22-carbon highly unsaturated fatty acids. Prostaglandins and leukotrienes produced from arachidonic acid (C20:4n-6) are required for blood clotting, cardiac function, reproduction, inflammatory response, and cell differentiation. Docosahexaenoic acid (C22:6n-3) is required for

Figure 2 Synthesis of highly unsaturated fatty acids.

cognition, brain development, and sperm biogenesis. Formation of bioactive 20- and 22-carbon highly unsaturated omega-6 and -3 fatty acids requires that the dietary essential fatty acids, linoleate and α -linolenate, undergo two steps of desaturation that are catalyzed by the Δ -6 desaturase (FADS1) and Δ -5 desaturase (FADS2). Both desaturases are expressed in all tissues. The human desaturase genes are members of a gene cluster on chromosome 11 that includes a third desaturase of unknown function (FADS3), and a noncoding RNA gene that encodes an anti-sense transcript for Δ -5 desaturase. Nearly all human tissues express the products of the Δ -6 desaturase gene cluster. Unlike the stearoyl-CoA desaturase, the Δ -6 and Δ -5 desaturases contain a cytochrome *b5* domain within the desaturase peptide. The rate of production of 20- and 22-carbon highly unsaturated fatty acids is dependent upon the tissue content of the two desaturases, and this in turn is determined by nutritional and hormonal factors that are similar to those that regulate the expression of lipogenic genes. The one notable difference between lipogenic and desaturase genes is that while HUFAs suppress both gene families, activators of peroxisome proliferator activator receptor- α induce desaturase genes but they suppress lipogenic genes. The increase in desaturase expression may be in response to a greater need for unsaturated fatty acids for the production of phospholipids, particularly in the liver for the secretion of very low density lipoproteins.

Glossary

Activated fatty acid The fatty acyl-CoA product of the acyl-CoA synthetase reaction. Activation allows the fatty acid to participate in most subsequent metabolic processes.

Acyl-CoA synthetase(s) Enzyme(s) found in all organisms that catalyzes the adenosine triphosphate (ATP)-dependent formation of a thioester bond between the carboxyl carbon atom of a fatty acid and the sulfhydryl sulfur atom of coenzyme A. Different enzymes show a general preference

for fatty acids of differing chain length, including short-chain, medium-chain, long-chain, and very long chain fatty acids.

Bubblegum acyl-CoA synthetase An acyl-CoA synthetase encoded by the defective gene in the *Drosophila melanogaster* mutant *Bubblegum*, and structurally related acyl-CoA synthetases found in other organisms.

Motif An amino acid sequence within a protein that is evolutionarily conserved. All known acyl-CoA synthetases possess two such motifs.

Fatty acids (FAs) are extremely diverse biomolecules. They serve, along with carbohydrates and proteins, as important metabolic fuels. They are constituents of numerous types of complex lipid, including triacylglycerol, phospholipids, plasmalogens, sphingolipids, glycolipids, and cholesterol esters. FAs can be converted to aldehydes and alcohols, and can be covalently attached to proteins. FAs can be remodeled by elongation, shortening, and the insertion or removal of double bonds. For essentially all of the reactions in which an FA participates, it must first be activated by conversion to its coenzyme A (CoA-SH) thioester (Figure 1). This activation reaction is catalyzed by a family of enzymes known as fatty acyl-CoA synthetases, or simply acyl-CoA synthetases (ACSs; EC 6.2.1.x).

The ACS reaction is a two-step reaction that proceeds by a unidirectional, bi uni bi ping-pong mechanism. In the first half-reaction, FA and adenosine triphosphate (ATP) react to form an acyl-adenylate, releasing inorganic pyrophosphate:

Hydrolysis of PP_i by inorganic pyrophosphatases effectively prevents reversal of this reaction. In the second half-reaction, CoA-SH displaces adenosine monophosphate (AMP), forming the acyl-CoA product:

The thioester linkage between the acyl group and CoA-SH is a high-energy bond that energetically facilitates subsequent reactions. Because AMP requires two phosphorylation steps to regenerate ATP, the ACS reaction consumes the equivalent of two ATP molecules.

A large number of different FAs, and FA-like compounds, that are ACS substrates exist in nature. The carbon chain length of FA in animals varies from 2 carbons (acetate) to about 28 carbons; some plant lipids contain FAs with more than 30 carbons. The FA carbon chain can be saturated, or contain one

or more double bonds. FAs can contain one or more methyl groups, forming branched-chain FAs. FA-like molecules that are ACS substrates include the bile acids and many xenobiotic compounds (e.g., nonsteroidal anti-inflammatory drugs). Because these FA substrates are molecularly diverse, multiple ACS isoforms have evolved to accommodate them.

ACS Families and Nomenclature

ACSs have been found in all organisms examined for their presence, including archaea, bacteria, yeasts, fungi, plants, invertebrates, fish, birds, and mammals. Early on, it was evident that there were distinct ACSs capable of activating FAs based roughly on their carbon chain length. They were described primarily as short-, medium-, and long-chain ACSs. It was subsequently recognized that ACS activities differed somewhat among the various tissues (e.g., liver vs. brain). Within a single tissue, distinct ACS activities were associated with different subcellular compartments; while the endoplasmic reticulum seemed to prefer long-chain FA substrates, mitochondria avidly utilized medium-chain FAs. Differing preferences for saturated versus mono- or polyunsaturated FAs of the same carbon chain-length were also reported. Thus by the beginning of the genomics era, evidence was emerging for the existence of a large number of distinct ACSs within a given organism.

Currently, the widespread availability of protein sequence databases has greatly facilitated the identification of ACSs. Many ATP-dependent enzymes whose reaction mechanism involves formation of an adenylated intermediate and liberation of PP_i have a characteristic amino acid sequence called the 'AMP-binding domain' (motif I; Figure 2). The presence of this sequence along with another more recently identified conserved amino acid sequence (motif II; Figure 2) predicts that a protein will have ACS activity with a high degree of accuracy. For example, firefly (*Photinus pyralis*) luciferase, well known for catalyzing an ATP-dependent bioluminescence reaction, contains motifs I and II. Luciferase has now been shown to be a bifunctional enzyme that also catalyzes the ATP-dependent synthesis

Figure 1 The fatty acyl-CoA synthetase (ACS) reaction. The ACS reaction catalyzes the ATP- and coenzyme A-dependent formation of fatty acyl-CoA. This activation process is necessary for the participation of FAs in the downstream metabolic processes illustrated. FA-CoAs are also regulators of enzyme activity and gene expression. One of the few reactions of FAs that does not require formation of the CoA-SH derivative is the conversion of the highly polyunsaturated FAs arachidonate and docosahexaenoate to bioactive eicosanoids and docosanoids, respectively.

Figure 2 Conserved amino acid sequence motifs in ACSs. All known ACSs from all species contain two highly conserved domains termed motif I and motif II. Motif I is an AMP-binding domain containing 10 amino acids; motif II contains 36–37 amino acids. To illustrate the evolutionary conservation of these domains, sequence logos were created from 36 ACS sequences: 26 were from humans and 10 were from the archaeobacterium *Archaeoglobus fulgidus*. In this representation, the height of each letter is proportional to the amino acid sequence conservation at that position. Thus, in motif I, both glycine (G) residues, as well as the proline (P) and lysine (K) are invariant in the 36 ACS sequences. Motif II is longer and shows more variation. The aspartate (D) at position 3 is invariant. The arginine (R) at position 18 is conserved in all but one of the 36 sequences, where it is a histidine (H) in human ACSBG2; this residue is otherwise 100% conserved in nature. Only hydrophobic amino acid residues are found at four positions in motif II, which are enclosed in boxes. For the 36 ACSs compared, consensus sequences are: motif I, (Y/F)TSGTTGPK, and motif II, TGD(X)₇G(X)₃hX(D/G)R(X)₄h(X)₃₋₄G(X)₂h(X)₃EhE, where X is any amino acid and h indicates any hydrophobic residue. Sequence logos were created using the Weblogo program, found at <http://weblogo.berkeley.edu>.

of long-chain fatty acyl-CoA. Motifs I and II are found in all known ACSs from archaeobacteria to man.

The genomes of humans and mice each encode 26 proteins predicted to be ACSs (Table 1). Enzyme activity has been

verified experimentally for nearly all of these proteins. Alignment of these ACS sequences – either the full amino acid sequence or only motif II – revealed that there are distinct families of ACSs in an organism. Three structurally related

Table 1 Human ACS families and nomenclature

Human ACS family	FA chain length preference	Members
ACSS	Short (2–4 carbons)	3
ACSM	Medium (4–12 carbons)	6
ACSL	Long (8–20 carbons)	5
SLC27A (ACSVL)	Very long (16–26 carbons)	6
ACSBG	16–18 carbons	2

families identified with no *a priori* knowledge of function contain enzymes historically identified as short-, medium-, or long-chain-specific ACSs. Additional ACS families in humans and mice include the very long chain and the BG ACS families.

The current nomenclature of ACSs is, in general, based on the chain-length preference of families of structurally related proteins (Table 1). For most enzymes, the root designation ACS is followed by a family designation (e.g., L for long chain) and a number that distinguishes the different members of a family. Thus, the three-member human short-chain ACS family includes ACSS1, ACSS2, and ACSS3. ACSs belonging to the very long chain family do not conform to the uniform nomenclature. These enzymes are also known as FA transport proteins (FATPs; see below), and their official symbol (SLC27Ax) and name (solute carrier family 27 (FA transporter), member x) is based on this. Not all ACSs in an organism are structural members of a specific family. Humans and mice each have four ACSs that fall into this category. They have been called ACS family member 1 (ACSF1) through ACSF4, although this is the official designation for only ACSF2 and ACSF3 (see below).

Conversely, not all organisms contain representatives of all ACS families. Roundworms (*Caenorhabditis elegans*) and yeast (*Saccharomyces cerevisiae*) do not have enzymes belonging to the ACSBG family. Fruit flies and roundworms have a large ACS family that is not found in humans, mice, zebrafish (*Danio rerio*), or yeast. Yeast (*S. cerevisiae* and *Schizosaccharomyces pombe*) have a unique enzyme that is also found in plants (*Arabidopsis thaliana*) and bacteria (*Mycobacterium tuberculosis*), but not in higher organisms.

Short-Chain ACSs

This and subsequent sections focus primarily on human and rodent ACSs; their genomes encode three ACSS family members. These enzymes generally activate FAs such as acetate, propionate, and butyrate that contain two to four carbon atoms. ACSS1 is a mitochondrial acetyl-CoA synthetase found in heart, skeletal muscle, kidney, lung, spleen, brain, and testis. ACSS2 is also expressed in many tissues and activates acetate, but is found in the cytosol. Both enzymes can activate the three-carbon FA, propionate, but to a lesser extent than acetate. ACSS3 has not been characterized, although it is predicted to be widely expressed in mammalian tissues. The likely function of these enzymes is to reactivate acetate (or propionate) produced primarily via the action of cellular acyl-CoA thioesterases.

Medium-Chain ACSs

Humans have six ACSM genes. Five are found in a cluster on chromosome 16, while the other is located on chromosome 12. Substrates for these enzymes generally contain 4–12 carbon atoms. All of the ACSM family members are found mainly in mitochondria. ACSM1, which is found in liver and kidney, activates FAs containing 4–14 carbons. However, the enzyme has maximal activity toward six- and eight-carbon saturated acids, and also activates several xenobiotic compounds such as benzoate and valproate. ACSM2 was also characterized as a xenobiotic kidney-specific ACS, although transcripts are also found in liver. In addition to xenobiotics, it activates FAs containing 3–10 carbons, and is maximally active with the six-carbon FA, hexanoate. ACSM2 actually refers to two closely related proteins named ACSM2A and ACSM2B. ACSM2A and 2B are encoded by distinct genes, one located on the (+) strand of chromosome 16 and the other on the (–) strand; however, their amino acid sequences are nearly identical, making it difficult to distinguish their individual biochemical properties.

ACSM3 was originally described the SA protein which is expressed at high levels in spontaneously hypertensive rats. Like ACSM1 and 2, ACSM3 is found mainly in liver and kidney. FA substrates ranging from three to eight carbons, including isobutyrate, are reportedly activated by this enzyme. The relevance of this enzyme to hypertension remains questionable, although a specific polymorphism has been related to blood pressure, serum cholesterol, and serum triglycerides in a population study. ACSM4 is an olfactory epithelium-specific medium-chain enzyme that activates FAs containing 6–12 carbons. The human ACSM4 gene resides on chromosome 12, apart from the cluster on chromosome 16 containing the other five ACSM genes. In contrast, the mouse ACSM4 gene is clustered with several other ACSM genes. The role of this enzyme in olfaction has not been established. Little is known about ACSM5. Transcripts are found mainly in liver and kidney, but also to a lesser extent in heart, muscle, mammary gland, testis, and other tissues.

Long-Chain ACSs

The most abundant FAs in nature contain 16–18 carbons; thus, many ACS studies have focused on the long-chain (ACSL) enzyme family members. These enzymes typically utilize FA substrates containing 8–20 carbon atoms. It should be recognized that there can be significant overlap in the substrate specificities of ACSL enzymes with both ACSM and ACSVL family enzymes, making assignment of ACS activity to a specific enzyme family difficult. Humans and mice express five different ACSL enzymes, ACSL1 and ACSL3–6. The designation ACSL2 is no longer used in order to reconcile the current nomenclature with historical references to specific long-chain ACSs in the literature.

ACSL1 has been widely studied. It is most abundant in liver, muscle, adipose, and heart. ACSL1 activates saturated FAs containing 10–18 carbons, as well as many long-chain mono- and polyunsaturated FAs. The protein is found mainly in endoplasmic reticulum and mitochondria-associated membranes (MAMs); plasma membrane and cytosol may contain some ACSL1 as well. Functionally, ACSL1 has been implicated

in hepatic triacylglycerol synthesis and mitochondrial FA β -oxidation; overexpression of this enzyme in heart also increased triacylglycerol synthesis. In adipose tissue, ACSL1 participates in FA reesterification following lipolysis, thereby affecting lipid efflux from fat cells.

ACSL3 is most highly expressed in brain, but is also found at lower levels in many other tissues. Its substrate specificity is somewhat similar to that of ACSL1, but the enzyme shows a high degree of specificity for the polyunsaturated FA, arachidonate. The function of this enzyme in brain is poorly understood. The enzyme is also found associated with lipid droplets in human hepatoma cells and mouse 3 T3-L1 adipocytes. In hepatoma cells, ACSL3 has been implicated in both very low density lipoprotein secretion and mitochondrial FA β -oxidation.

Like ACSL3, ACSL4 shows a high level of substrate specificity for arachidonic acid; this enzyme also activates other polyunsaturated FAs. The enzyme is highly expressed in heart, brain, placenta, muscle, kidney, spleen, adrenal gland, testis, and ovary. Also similar to ACSL3, ACSL4 was found associated with lipid droplets in a human liver cell line. Subcellular fractionation of rat liver showed that the enzyme is also located in peroxisomes and MAMs. The latter location suggests a role for ACSL4 in triacylglycerol synthesis. This enzyme has also been implicated in steroidogenesis in several tissues. Mutations in ACSL4 are associated with X-linked mental retardation in some patients.

The mitochondrial enzyme ACSL5 is expressed in several tissues, including liver, spleen, uterus, intestine, colon, and leukocytes. Its substrates include saturated 10- to 20-carbon FAs, as well as long-chain monounsaturated and polyunsaturated FAs. ACSL5 is variably associated with some human cancers; its expression was markedly increased in human glioblastomas and glioma cell lines, but was decreased in small intestine epithelial tumors.

In rodents, ACSL6 was formerly known as ACSL2. This enzyme is capable of activating long-chain saturated, monounsaturated, and polyunsaturated FAs. The main human tissues expressing ACSL6 are brain and erythrocyte precursor cells. A differential splicing event produces two variants of ACSL6 that differ in the amino acid sequence of one exon; one variant is brain specific, while the other is found in blood cell precursors. The brain variant of ACSL6 is upregulated in the frontal cortex in a rodent model of depression; this enzyme may participate in neuronal cell proliferation and differentiation. Mutations in the hematopoietic variant of ACSL6 have been associated with acute myelogenous leukemia in several patients.

Very Long Chain ACSs

The human and mouse very long chain ACS families each have six members. In general, these enzymes are capable of activating long- to very long chain FAs (containing 16–26 carbons); thus, there is significant substrate specificity overlap with ACSL family enzymes. The designations of these ACSs in the literature using the ACSVL nomenclature have been inconsistent; therefore, they are described herein using their official gene/protein names. SLC27A1 (also known as FATP1 and ACSVL4) was identified in a screen for proteins that facilitated uptake of long-chain FAs by cultured cells. Thus, it was initially called FATP. This protein was subsequently shown to have ACS

activity. It activates FAs containing 16–24 carbons, and is found in muscle, heart, brain, and adipose tissue. Subcellular locations include endoplasmic reticulum, mitochondria, plasma membrane, and cytoplasmic vesicles. Functionally, SLC27A1 has been implicated in triglyceride synthesis and mitochondrial β -oxidation. Expression is upregulated during adipocyte differentiation. Heart-specific overexpression of SLC27A1 in mice resulted in the increased uptake of long-chain FAs and lipotoxicity, suggesting a role in maintaining normal FA levels in cardiomyocytes.

SLC27A2 (also known as FATP2 and ACSVL1) is a liver- and kidney-specific ACS. This enzyme was the first very long chain specific ACS isolated from a tissue source – rat liver peroxisomes – using classical protein purification methodology. It activates FAs containing 16–24 carbons, and is also found in the endoplasmic reticulum. In peroxisomes, SLC27A2 activates FAs to provide substrates for the β -oxidation pathways found in that organelle. Bile acid precursors derived from cholesterol, which undergo one cycle of peroxisomal β -oxidation in their conversion to bile acids, are also SLC27A2 substrates. The function of this enzyme in the endoplasmic reticulum is unknown.

SLC27A3 (also known as FATP3 and ACSVL3) expression is most abundant in brain and steroidogenic tissues. Its substrate specificity is similar to that of SLC27A1. The enzyme is found in small cytoplasmic vesicles that have not yet been characterized. SLC27A3 expression is highly upregulated in human malignant gliomas and cultured glioma cells; knockdown of the enzyme by RNA interference reduced the malignant properties of tumors and cells.

Brain, adipose tissue, skeletal muscle, heart, and small intestine are the primary tissues expressing SLC27A4 (also known as FATP4 and ACSVL5). Substrates activated by SLC27A4 are similar to those activated by SLC27A1 and A3, but this enzyme seems to have a greater preference for the very long chain FAs. SLC27A4 and SLC27A1 share considerable amino acid identity, and both have been implicated in the cellular uptake of long-chain FAs. Unlike SLC27A1, however, which is partially located in plasma membrane, SLC27A4 is in peroxisomes, MAMs, and endoplasmic reticulum, but not in plasma membrane, reducing the likelihood of a role in FA uptake. In skin fibroblasts, this enzyme is required for incorporation of very long chain FAs (but not long-chain FAs) into triglycerides and phospholipids, and is needed for the peroxisomal β -oxidation of very long chain FAs. Polymorphisms in SLC27A3 have been associated with obesity and insulin resistance in some human population studies.

Bile acids, and not FAs, are the primary substrates for the liver-specific enzyme SLC27A5 (also known as FATP5, ACSVL5, and BACS). For conjugation to taurine or glycine, bile acids must first be activated to their CoA-SH derivatives. In liver hepatocytes, SLC27A5 is found in the basal plasma membrane. Although this enzyme only weakly activates FA substrates, mice deficient in SLC27A5 have reduced triglyceride and free FA levels in addition to reduced levels of conjugated bile acids. SLC27A5-deficient mice also have decreased food intake and increased energy expenditure.

SLC27A6 (also known as FATP6 and ACSVL2), characterized initially as a heart-specific protein, is also detected in hair follicle epithelia. The protein is found on the sarcolemma of cardiomyocytes near small blood vessels. Like most other

members of the family, long-chain to very long chain FAs are the primary substrates of SLC27A6. The function of this enzyme is not known.

The Bubblegum or BG ACS Family

The fruit fly (*D. melanogaster*) "Bubblegum" mutant, characterized by neurodegeneration and elevated levels of saturated very long chain FAs, has a defect in the gene encoding an ACS that does not belong to any of the families listed above. Humans, mice, and fruit flies each have two ACSBG family enzymes. Human ACSBG1 is found only in neurons in the brain and spinal cord, and in steroidogenic cells within the adrenal cortex, testis, and ovary. Like SLC27A3, ACSBG1 is contained within an uncharacterized population of small cytoplasmic vesicles. While most ACSs activate a range of FAs both shorter and longer than their optimal substrate, ACSBG1 has a unique preference for the 16-carbon saturated FA, palmitate. A role for this enzyme in the human disorder, X-linked adrenoleukodystrophy, has been hypothesized but not proven. There is some evidence for a role of ACSBG1 in the regulation of testicular steroidogenesis.

The tissue expression of ACSBG2 is limited to the testis, particularly Sertoli cells, and large motoneurons of the brainstem and cervical spinal cord. Preferred FA substrates are 18-carbon FAs containing one (oleate) or two (linoleate) double bonds; these are the most abundant FAs in testis. A role for ACSBG2 in spermatogenesis has been suggested.

Other Human and Mouse ACSs

Four proteins containing structural features of ACSs, including motifs I and II, but that do not belong to any family above, are found in mice and men. These are referred to as ACSF (ACS family) proteins. ACSF1 (official symbol, AACS) is acetoacetyl-CoA synthetase. It is a cytosolic protein found mainly in brain and kidney, with moderate levels in heart, skeletal muscle, and placenta. The proposed function of this enzyme is in cholesterol biosynthesis. Little is known about ACSF2 and ACSF3; the former prefers medium-chain FA substrates, whereas the latter activates the 24-carbon very long chain FA, lignocerate. ACSF4 (official symbol, AASDH) is amino adipate-semialdehyde dehydrogenase. Its reaction mechanism involves an adenylated amino adipate intermediate, and the enzyme itself is covalently modified by the addition of a phosphopantetheine group donated by CoA-SH. However, the ability of AASDH to function as an ACS and activate FA substrates has not been demonstrated.

ACS Structure–Function Considerations

Human ACSs, excluding the unusually long putative ACS, ACSF4/AASDH, contain 576–739 amino acids (average: 656). The relative positions of motifs I and II (Figure 2) within ACS amino acid sequences are highly conserved. The initial residue of motif I is found at approximately amino acid 261 (range: 201–334). The average distance between this residue and the

conserved arginine (R) of motif II is 263 amino acids (range: 241–293). Motifs I and II are found in all known ACSs and are highly conserved throughout evolution, suggesting that they are necessary for catalytic function. Mutagenesis of specific residues in motifs I and II of ACSs from yeast, bacteria, and plants confirmed that several amino acids in these domains are critical for enzyme activity. In addition to motifs I and II, there are at least three additional conserved domains that are present in subsets of ACSs. For example, a motif with consensus sequence LPLXH (where X is any amino acid) is found in all human ACSL, SLC27A, and ACSBG family members, but not in any of the ACSS or ACSM enzymes.

No crystal structure for a mammalian ACS was available until 2009, when the structure of the human medium-chain enzyme, ACSM2A, was published. Crystal structures of three ACSs from lower organisms have also been determined. Two are short-chain ACSs, one from the yeast *S. cerevisiae* and the other from the bacterium *Salmonella enterica*. The structure of a long-chain ACS from the extreme thermophile *Thermus thermophilus* has also been solved.

Human ACSM2A crystallizes as a monomer, whereas the yeast and bacterial enzymes crystallize as dimers or trimers. All monomeric units have a characteristic two-domain structure, consisting of a larger N-terminal portion and a smaller C-terminal domain linked by a hinge region. Catalysis occurs at the interface of the two domains. The C-terminal domain assumes different conformations during the catalytic cycle, rotating 135–140° between the first (acyl-adenylate forming) and second (thioester forming) half-reactions. Release of PP_i by the first half-reaction is thought to trigger this conformational switch.

Motifs I and II are located in the larger N-terminal domain of ACSs. Crystal structures indicate that residues comprising motif I are in close proximity to the adenosine moiety of AMP, maintaining it in the proper orientation. Similarly, the highly conserved arginine (R) residue at the center of motif II is in proximity to ribose hydroxyl groups in AMP, again maintaining the spatial orientation of the adenylate group.

The LPLXH motif of human ACSs described above is located between motifs I and II, and is thus also in the large N-terminal domain. This motif is homologous to a region described as the gate motif in the *T. thermophilus* long-chain ACS. FA binding to the enzyme promotes opening of the gate, allowing access to the ATP-binding site for acyl-adenylate formation. This motif is not present in human ACSS or ACSM enzymes, nor is it found in the yeast or bacterial acetyl-CoA synthetases noted above, suggesting that it is more critical to enzymes that prefer longer-chain FA substrates.

There is a highly conserved lysine residue found near the end of the small C-terminal domain of ACSs. This residue is critical for both catalysis and regulation of enzyme activity. In the first half-reaction, a salt bridge between the epsilon amino group of the conserved lysine and the β-phosphate oxygen atoms of ATP helps position the latter compound for nucleophilic attack by the FA substrate. Following rotation of the C-terminal domain, the lysine residue is located on the exterior surface of the protein, where it remains during the second half-reaction. In some short-chain ACSs, acetylation of the epsilon amino group occurs, effectively rendering the enzyme catalytically inactive. Deacetylation catalyzed by sirtuins restores activity. Although

all ACSs seem to retain the conserved lysine near the C-terminus, regulation of ACSs that activate longer chain FAs by this mechanism has not been demonstrated.

Concluding Remarks

The ACSs comprise a large family of enzymes that must accommodate the diverse nature of both the FA substrates they activate, and the downstream processes in which their products participate. The presence of multiple members of the ACSs, ACSM, ACSL, and SLC27A suggests the possibility that each serves at unique positions in metabolism, providing fatty acyl-CoAs for specific anabolic or catabolic pathways. This is accomplished via substrate specificity, tissue and cellular expression patterns, and subcellular distribution. The specific functions of ACSs in metabolism are only beginning to be understood. As new observations on ACSs are reported, it is clear that these enzymes perform many unique functions, and are critical for the maintenance of normal cellular FA and lipid homeostasis.

Glossary

Iron-sulfur cluster A prosthetic group containing iron and sulfur atoms liganded by protein-cysteine residues.

Isoform Any of multiple forms of a protein differing in primary structure but having similar function.

Photosynthesis A process that converts the light energy into the chemical energy of nicotinamide adenine dinucleotide phosphate, reduced form (NADPH) and adenosine triphosphate (ATP).

Thioredoxin A small protein containing an oxidoreducible disulfide.

2Fe Ferredoxins

The 2Fe ferredoxins (Fds) are hydrophilic, acidic proteins of 11–15 kDa which harbor a single 2Fe–2S cluster coordinated by four cysteine residues. They function as single-electron shuttle in fundamental metabolic processes. The family can be subdivided into two major classes, the mitochondrial-type and the plant-type Fds, based on the cysteine spacing in the iron-sulfur binding motif, the three-dimensional (3D) structure, and function. A third class of bacterial 2Fe-Fds has recently been recognized on the basis of sequence and spectroscopic properties.

Plant-Type 2Fe Fds

More than a hundred sequences of 2Fe Fds have been deposited in sequence databases. The polypeptide chain is 93–98 residues long, yielding a protein of molecular mass of ~11 kDa. Plants as well as the single-celled green algae contain several Fd isoforms (up to six) at variance with cyanobacteria which host just one Fd in the vegetative cells and an isoform in the heterocysts. In photosynthetic cells, the main role of Fd is the electron transfer from photoreduced photosystem I (PSI) to Fd-NADP⁺ reductase (FNR), as well as a distribution of electrons to a large number of Fd-dependent enzymes involved in regulatory and assimilatory pathways (Figure 1). The archetype of this class is the chloroplast ferredoxin I (FdI) which is encoded by the PET F gene. Under normal growth conditions, the PET F transcript in the green alga *Chlamydomonas reinhardtii* constitutes 98% of the total Fd-encoding transcript.

Molecular Structure

The characteristic spacing of the cysteinyl residues in the iron-sulfur-cluster-binding motif for this class is C-X₄-C-X₂-C, which provides three of the four thiolate ligands to the two iron atoms, with the fourth ligand 29 residues downstream in the primary structure. Several Fds have been structurally characterized by either X-ray crystallography or nuclear magnetic resonance (NMR) spectroscopy. They show a folding motif, dubbed β -grasp, which is similar to that of ubiquitin. It is constituted by a

four-stranded antiparallel β -sheet and an α -helix lying perpendicularly to the sheet. A representation of the structure of recombinant spinach FdI is depicted in Figure 2 to show the secondary structure elements. The central core (β -grasp) holds the loop which harbors the Cys motif for binding the iron-sulfur cluster. In addition, two short β -strands, a second α -helix, and a short C-terminal helical turn are present. The binuclear iron cluster is located near the surface of the protein with Fe1 atom more exposed to solvent. Upon protein reduction, Fe1 has been shown to become reduced. The surface of the Fd molecule shows an asymmetry in distribution of the many acidic residues, which cluster in two distinct areas around the FeS prosthetic group. This feature common to all plant-type Fds has been shown to be important for interaction with protein partners.

Physiological Function

The nuclear-encoded FdI is imported in the chloroplast as an apoprotein, where it acquires the prosthetic group. FdI biosynthesis is under the control of light. As depicted in Figure 1, FdI forms transient electron transfer complexes with several different proteins. First, it is reduced through electron transfer from the 4Fe–4S center F_B of the subunit PsaC of PSI, by docking to both the PsaD and the PsaE subunits at the stromal side of the thylakoid membrane. Then, the reduced protein donates its electron to either one of the various enzymes known to be Fd dependent. It is conceivable that some of these functions may be performed by a specific isoform of Fd. NADPH production through Fd-NADP⁺ reductase (FNR) is the main role of FdI. Several studies employing a number of different techniques have attempted to define the binding region of FdI for its various redox partners. The 3D structure of the Fd-FNR complexes from both *Anabaena* spp. and maize has recently been obtained. Overall, the picture which comes out is that FdI acts as a mobile electron shuttle between PSI and the enzyme partners, utilizing for the interaction the same acidic surface area surrounding the iron-sulfur cluster. The binding sites need not be exactly the same but may be just overlapping.

Fd isoforms are also present in plastids of nongreen plant tissues and, recently, such a type of Fd has been found in the organelle called 'apicoplast' of protozoan parasites Apicomplexa (*Plasmodium* spp., *Toxoplasma gondii*, etc.). These Fds, which have a more positive redox potential than the photosynthetic

The figure was prepared using Molmol.

ones, are reduced by FNR isoforms at the expense of NADPH and act as reductant of Fd-dependent pathways in these organelles.

Mitochondrial-Type 2Fe Fds

Mammalian adrenodoxin (Adx) is the prototype of this class; other well-known members are putidaredoxin of *Pseudomonas putida*, yeast Fd, and *Escherichia coli* Fd. The first two Fds have the role of providing electrons to cytochrome P450-catalyzed hydroxylation reactions, the latter two have been more recently implicated in iron-sulfur cluster biogenesis. They are 105–128 residues long, thus are up to 4 kDa larger than plant Fds. The typical Fe-S-binding sequence is C-X₅-C-X₂-C, which provides three of the four thiolate ligands to the iron atoms, with the fourth ligand 35–37 residues downstream in the sequence. The 3D structures of these Fds show high similarity to those of the plant Fds in the fold of the core involving the N-terminal moiety (i.e., the β -grasp), but they have an additional C-terminal lobe, called ‘interaction domain’, which has been shown to be involved in binding both the redox partners, Adx reductase and cytochrome P450. As in the case of FdI, the binding sites may be separate but overlapping.

Thioredoxin-Type 2Fe Fds

Thioredoxin-like Fds (also dubbed Shethna subtype) were first identified in *Azotobacter vinelandii* and *C. pasteurianum*. They seem to be present only in bacteria. The polypeptide chain length is that usually reported for 2Fe Fds, that is, 100–120 residues, but these Fds, being dimer, have a larger molecular mass. The cysteine motif for binding the iron-sulfur cluster is rather unique: C-X₁₀₋₁₂-C-X₂₉₋₃₄-C-X₃-Cys and the crystal structure of *Aquifex aeolicus* Fd revealed a fold unusual for Fds and quite similar to that of thioredoxin. The function of these Fds is not yet known, although there are some indications for their involvement in nitrogen fixation.

Fds Containing 4Fe and 3Fe Iron-Sulfur Clusters

This class comprises 3Fe, 4Fe, 7Fe, and 8Fe Fds, which are small, bacterial proteins containing one or two FeS clusters of the cubane type. The iron and sulfide atoms alternate on the corners of a distorted cube. In the case of the 3Fe cluster, one corner is devoid of the fourth iron atom. The two types of clusters are in some cases interconvertible. The cysteine motif for the coordination of these iron-sulfur centers is C-X₂-C-X₂-C with the middle cysteine replaced by aspartic acid or any residue in the case of 3Fe clusters, in a polypeptide chain of 60–100 residues. The 8Fe Fds constitute the largest family of this class of Fds. Their structure highlights a pseudo-twofold symmetry of the molecule which reflects an ancient sequence duplication. All 7Fe and 8Fe Fds are phylogenetically related. They all share a very similar [Fe-S] cluster-binding core of about 55 amino acids folded according to a conserved ($\beta\alpha\beta$)₂ structure topology. Nevertheless, outside the cluster-binding core, the Fds show a high level of structural variability. All these Fds generally function as electron carriers in several

metabolic pathways, including pyruvate metabolism, nitrogen fixation, sulfate reduction, hydrogen production, and cytochrome P450 hydroxylations.

Glossary

Domain An independently folded structural region of a protein molecule.

Flavoprotein A protein that contains a flavin nucleotide (flavin adenine dinucleotide (FAD) or flavin mononucleotide (FMN)) as prosthetic group.

Photosynthesis A process that converts the light energy into chemical energy of NADPH and adenosine triphosphate (ATP).

Prosthetic group A tightly bound cofactor that contributes to the biological activity of a protein.

Rossmann fold A protein structural motif for nucleotide binding.

Introduction

Ferredoxin-NADP⁺ reductase (FNR) is the common name of members of a broad group of flavoenzymes (classified as EC 1.18.1.2) sharing the ability to catalyze the transfer of reducing equivalents between NADP(H) and ferredoxins (Fds). The best-known example is the photosynthetic FNR, the terminal component of the photosynthetic electron transport chain, in both eukaryotic and prokaryotic phototrophic organisms. In addition to this photosynthetic oxidoreductase, isoforms exist in nonphotosynthetic cells. The subdivision between photosynthetic and nonphotosynthetic FNRs is functional, and is based on the physiological direction of the catalyzed reaction, that is, toward NADP⁺ reduction in the case of photosynthetic FNR and toward Fd reduction for heterotrophic FNRs (Figure 1). Besides such functional classification, a structural/phylogenetic one is possible, which distinguishes between plant-type and glutathione reductase (GR)-type FNRs. While all photosynthetic FNRs are plant-type, nonphotosynthetic reductases are distributed between both structural classes.

Furthermore, the plant-type FNR is the prototype of a large superfamily of homologous enzymes, which display a great variety of catalytic functions. All members of this family possess the two-domain FNR unit and additional domains that modify and extend their functional properties.

Photosynthetic FNR

FNR was first discovered in 1956 by Avron and Jagendorf, who isolated it from pea chloroplasts as an NADPH-dependent diaphorase (i.e., a flavin-containing enzyme that catalyzes the transfer of reducing equivalents from NADPH to various electron acceptors). This chloroplast oxidoreductase was later shown by Shin and Arnon to mediate the transfer of electrons from ferredoxin to NADP⁺.

Molecular Structure

Photosynthetic FNRs are monomeric proteins of about 35-kDa molecular mass, containing one molecule of noncovalently but tightly bound flavin adenine dinucleotide (FAD) as prosthetic group. FNRs from different eukaryotic sources show a

high sequence similarity (~80% identity), which is spread over the entire polypeptide chain of ~300 amino acid residues. Cyanobacterial FNR possesses an additional N-terminal sequence of ~10 kDa involved in binding to phycobilisomes, light-harvesting structures of the thylakoid membrane of cyanobacteria. The three-dimensional (3D) structures of photosynthetic FNRs have been determined at high resolution (up to 1.7 Å) by X-ray crystallography for the proteins from spinach, pea, paprika, and maize leaves, as well as from the cyanobacterium *Anabaena* spp. The enzyme molecule consists of two structural domains, each of ~150 residues (Figure 2). The N-terminal domain, comprising a six-stranded antiparallel β-barrel, a small β-sheet, and an α-helix, provides most of the residues involved in FAD binding and is thus also known as the FAD-binding domain. The C-terminal domain, topologically similar to the supersecondary structure named 'Rossmann fold', binds NADP(H) and is thus indicated as the NADP-binding domain. However, both dinucleotides interact also with residues belonging to the other domain. Indeed, FAD- and NADP(H)-binding sites are located within a deep cavity at the interface of the two domains. The isoalloxazine ring of FAD, as in many flavoproteins, is sandwiched between the side chains of two aromatic residues. In particular, the C-terminal tyrosine residue makes an aromatic stacking interaction with the *re*-face of the isoalloxazine ring.

Subcellular Localization and Physiological Role

FNR is present in the chloroplasts of algae and higher plants. It is an extrinsic membrane protein localized on the side facing the stroma of the thylakoid membrane. FNR is the catalyst of the last step in the light-driven electron transport. FNR is thus directly responsible for producing the NADPH required in the Calvin cycle for carbohydrate biosynthesis. Reducing power is in turn provided to FNR by Fd, which acts as an electron shuttle by diffusing in the stroma between photosystem I and FNR and being reduced by the former and oxidized by the latter.

Catalytic Mechanism

FNR catalyzes the reversible transfer of reducing equivalents between the obligatory one-electron carrier ferredoxin (Fd)

Figure 1 Comparison of the physiological reactions catalyzed by photosynthetic and nonphotosynthetic FNR isoforms. (a) Scheme of the reaction catalyzed by FNR in chloroplasts. PSI, photosystem I; FdL, photosynthetic isoform of Fd. (b) Scheme of the reaction catalyzed by nonphotosynthetic FNR isoforms. Fd indicates any nonphotosynthetic Fd isoform, including adrenodoxin. The dashed line indicates the electron transfer path.

Figure 2 Ribbon model of the 3D structure of the pea photosynthetic FNR mutant with a serine replacing the C-terminal tyrosine residue. The FAD-binding and the NADP-binding domains are depicted in orange and green, respectively. The wireframes of bound FAD and NADP⁺ are shown in yellow and cyan, respectively. The figure was prepared using Molmol.

and the obligatory two-electron carrier NADP(H), according to the following balanced chemical equation:

The ability of FNR to pair single electrons in order to transfer them as a couple to a two-electron acceptor is a feature of the dehydrogenase-electron transferases class of flavoproteins to which FNR belongs, and is mediated by the FAD prosthetic group. FAD can exist in three redox states: oxidized, one-electron reduced (semiquinone form), and two-electron reduced (dihydroquinone form). During turnover, enzyme-bound FAD cycles among the three redox states described above, according to the reaction scheme shown in Figure 3.

Figure 3 Simplified scheme of the mechanism of the reaction catalyzed by the photosynthetic FNR isoform. FdL indicates the photosynthetic Fd isoform present in chloroplasts. FdL_{ox} and FdL_{red} indicate oxidized and reduced forms of FdL, respectively. FADH[•] and FADH⁻ indicate the neutral semiquinone and the hydroquinone anion of FAD, respectively.

Two reduced Fd molecules sequentially transfer one electron at a time to FAD, before FNR can complete the catalytic cycle transferring a couple of electrons to NADP⁺. Electron transfer is strictly coupled to proton (H⁺) transfer, at least in steps 2 and 4. FAD protonation in step 2 is required to yield the neutral semiquinone form observed during turnover. In step 4, two electrons are transferred simultaneously with one H⁺ in the form of a hydride ion (H⁻). Catalysis proceeds according to a sequential-ordered mechanism, through the formation of ternary complexes of FNR with both substrates. The redox potential of the FAD/FADH[•] couple in FNR is -360 mV, a value intermediate between that of FdL (-400 mV) and that of the NADP⁺/NADPH couple (-320 mV).

Interaction with NADP(H)

FNR is a remarkably specific enzyme, showing a strong preference for NADP⁺ over NAD⁺. Substrate discrimination is due to a number of interactions that FNR establishes with the 2'-phosphate group of NADP(H). NADP(H) interactions with FNR have been described in terms of a bipartite binding mode, where the adenylate moiety of the dinucleotide binds independently of the nicotinamide one. Binding of the adenylate moiety occurs with high affinity and is the leading event in substrate recognition. In order to allow hydride transfer to occur between the reduced isoalloxazine ring and the nicotinamide, FNR has to undergo an induced-fit process where the nicotinamide ring of NADP⁺ displaces the phenol ring of the C-terminal tyrosine residue from its stacking interaction with *re*-face of the isoalloxazine (Figure 2). A detailed picture of the enzyme-NADP(H) interaction has been obtained by producing an engineered FNR, where the C-terminal tyrosine was changed to a nonaromatic residue. This greatly stabilized the interaction between the flavin and the nicotinamide ring. Thus, X-ray crystallography of the NADP(H) complex with the mutant FNR revealed the hydride-transfer-competent-binding mode of the substrate (Figure 2).

Figure 4 Ribbon model of the binary complex between maize photosynthetic FNR and FdI. FNR is depicted in cyan, while FdI is in red. The wireframe of FAD is shown in yellow. The iron–sulfur cluster is represented as a ball and stick model, with the iron atoms in brown and the sulfur atoms in yellow. The figure was prepared using Molmol.

Interaction with Fd

Crystals of the complexes between FNR and Fd, both in the oxidized state, have been obtained for the eukaryotic (maize leaf and root) and the prokaryotic (*Anabaena* spp.) protein couples. X-ray structures are similar (Figure 4). Fd binds to a large concave region of FNR, which is contributed by both structural domains of the reductase, with the FAD-binding domain providing most of the interactions. Complex formation places the redox active prosthetic group at a distance (6.0–7.4 Å) compatible with high-rate electron transfer. Protein–protein complex formation is thought to be initially driven by the mutual orientation of the dipole moments of the two molecules as they approach. After initial docking, minor adjustments are expected to occur to reach a conformation optimal for intermolecular electron transfer, with the formation of a network of intermolecular weak bonds (salt bridges, hydrogen bonds, van der Waals, and hydrophobic interactions). Charge–charge interactions, which play a major role in the stabilization of the Fd–FNR complex, are formed between basic groups provided by FNR and acidic groups of Fd.

Nonphotosynthetic Plant-Type FNRs

Root FNR

Nonphotosynthetic plastids of higher plants contain an isoform of FNR, also known as ‘root FNR’. Root and leaf isoforms of FNR are clearly homologous, showing a sequence identity of ~48%, which corresponds to highly similar 3D structures. Isoform-specific differences are limited to the structure of surface loops of the molecules, the presence of a conserved disulfide bridge in the FAD-binding domain of the root isoform, a higher redox potential for the bound FAD of the root isoform, and different affinities for the Fd isoforms. Many of these structural and functional differences are instrumental for the diverse physiological role played by the two FNR isoforms. Indeed, the role of root FNR is opposite to that of the leaf isoform, that is, transfer

of reducing equivalents from NADPH to a root-specific Fd isoform to yield reduced Fd for several Fd-dependent pathways.

Bacterial and Apicomplexan FNR

FNRs belonging to the FNR structural family are present in some prokaryotic organisms such as *Escherichia coli* and *Azotobacter vinelandii*. A plant-type FNR has been recently identified in different species belonging to the *Apicomplexa*, a phylum of obligatory eukaryotic unicellular parasites, including the causative agents of malaria, toxoplasmosis, and coccidiosis. In the apicomplexan cell, the FNR is localized, together with a plant-type Fd, in a peculiar organelle, the apicoplast. Apicomplexan FNR is thus expected to play a metabolic function similar to that of root FNR, that is, production of reduced Fd to be used in reductive biosynthetic pathways. In particular, the apicoplast FNR/Fd electron transport system has been experimentally shown to be involved in the biosynthesis of isoprenoid precursors and in heme degradation. Due to the increasing importance attributed to the apicoplast metabolism in parasite pathogenicity, apicomplexan FNR is an attractive target for novel antiparasitic drugs.

Heterotrophic GR-Type FNRs

In addition to plant-type FNRs, various FNRs exist that – while being structurally and phylogenetically distinct from the former – show essentially the same catalytic activity, thus representing a noteworthy example of convergent evolution. Such FNRs show a significant sequence identity. The 3D structures of two of them (bovine adrenodoxin reductase and *Mycobacterium tuberculosis* FprA) have been determined and shown to be similar to that of GR. FNRs of the GR-like class thus have both domains based on the Rossmann fold motif for binding the nucleotides (FAD and NADPH). The prototype of such enzymes is adrenodoxin reductase (AdR), found in vertebrate mitochondria, where it transfers electrons from NADPH to an Fd known as adrenodoxin (Adx). AdR and Adx form an electron supply system for the cytochrome P450-catalyzed hydroxylation reactions to produce steroid hormones, vitamin D metabolites, and bile acids. An AdR-homologous protein (Arh1) has been recently found in *Saccharomyces cerevisiae*. By now, AdR and Adx have been shown to be ubiquitous in mitochondria of eukaryotes, where they play a role in the biogenesis of iron–sulfur clusters. More recently, an AdR-like enzyme (FprA) has been identified in *M. tuberculosis*, showing that they are not restricted to eukaryotes. FprA is thought to play a crucial role in the complex lipid metabolism of this pathogen as a source of reducing power for the unusually large numbers (~20) of cytochromes P450 present in this organism. This observation could eventually lead to novel pharmacological treatment for tuberculosis.

Glossary

Malignant transformation Process of exhibiting qualities of malignancies including uncontrolled growth, anchorage-independent cell growth, and *in vivo* tumor formation.

mRNA splice variant An isoform of a protein resulting from the processing of different exons of a gene.

Fibroblast growth factors (FGFs) constitute a family of homologous heparin-binding polypeptides that presently consists of at least 23 members. FGFs play important roles in many biological functions, including development, pattern formation, cellular differentiation, metabolic regulation, tissue repair, angiogenesis, and mitogenesis. FGFs act by binding to a family of specific, high-affinity FGF receptors (FGFRs) that possess a discontinuous intracellular kinase domain. Perturbations in FGF–FGFR expression, localization, and signaling have been implicated in several pathological processes, including malignant transformation and tumor spread and metastasis.

Fibroblast Growth Factors

Genes

In vertebrates, 23 *Fgf* genes have been identified. Human *Fgf15* has not been described. Human *Fgf19* is most closely related to mouse *Fgf15* raising the possibility that human *Fgf19* may be identical to mouse *Fgf15*. Both genes are closely linked to the *Fgf3* and *Fgf4* genes. According to their evolutionary relationship, the 22 *Fgfs* in humans can be classified into several subgroups (Figure 1). Members of each subgroup may also share similar biochemical and developmental properties. For example, members of the *Fgf8* subgroup display similar receptor-binding properties and overlapping, yet distinct expression patterns during development, underscoring both their commonality and uniqueness.

Proteins

Among vertebrates, FGFs share 13–71% of their amino acid sequence homology. Most notably, there is an internal core region consisting of six identical and 28 highly conserved amino acids, which include the 10 amino acid residues interacting with the high-affinity FGFRs within an approximately 120 amino acid region. In FGF-1 and FGF-2, this area consists of 12 anti-parallel beta strands forming a structure exhibiting a threefold internal symmetry called a 'beta-trefoil'.

FGF-4–8, -10, -17–19, -21, and -23 all possess classical N-terminal leader sequences that may allow for rapid and efficient secretion. This sequence is also present in FGF-3 and -22. However, they are not efficiently secreted. By contrast, FGF-1, -2, -9, and -11 to -14, -16 and -20 lack a leader sequence for secretion. Nonetheless, FGF-9, -16, and -20 have a

hydrophobic region in the core domain allowing for secretion. Moreover, FGF-1 and FGF-2 may be released by an exocytotic mechanism, while FGF-11–14 are thought to remain intracellularly. As these four family members do not function as FGF ligands, they are also referred to as 'FGF homologous factors'. Posttranslational glycosylation, alternative splicing, and initiation of synthesis from N-terminal cytosine–uridine–guanine (CUG) sequences can result in several different molecular weight forms in the case of several FGFs.

Physiologic Actions

FGFs regulate diverse processes during developmental processes and exert a broad variety of functions in the adult organisms, including growth, survival, apoptosis, motility, and differentiation.

Fibroblast Growth Factor Receptors

Genes

FGFRs are glycoproteins encoded by four distinct *Fgfr* genes. A special feature of the FGFR family is the existence of several receptor isoforms for FGFR-1, -2, -3, and -4 that are generated by alternative messenger RNA (mRNA) splicing and result in different ligand-binding specificities. A fifth related receptor, *FGFR5* (also known as 'FGFRL1'), can bind FGFs, but is devoid of an intracellular kinase domain. The function of FGFR-5 which is also devoid of intracellular signaling capacity is presently unknown, but it may provide a binding site for FGFs.

Proteins

FGF signaling is generally mediated by a dual-receptor system, consisting of the high-affinity FGFRs and low-affinity heparan sulfate proteoglycan (HSPG) chains enhancing ligand presentation to the receptors. The structure of an FGF–FGFR complex is composed of two FGFR chains, two FGFs, and an HSPG chain. FGFRs are related to vascular endothelial growth factor receptors and platelet-derived growth factor receptors. The extracellular domain is usually composed of three immunoglobulin (Ig)-like domains (I–III), including a stretch of acidic residues (acidic box) between domain I and II, which is unique for the FGFRs. The hydrophobic transmembrane region is followed by a juxtamembrane domain and a split tyrosine kinase catalytic

Figure 1 Evolutionary relationships within the human FGF family. Adapted from Ornitz DM and Itoh N (2001) Protein family review: Fibroblast growth factors. *Genome Biology* 2: 3005.1–3005.12.

domain (Figure 2). Most notably, alternative splicing of the second half of the Ig-like domain III results in three receptor variants, termed IIIa, IIIb, and IIIc (Figure 2). Due to the fact that the ligand-binding pocket is formed by Ig-like domains II and III, these splice are important for defining ligand-binding specificity. The first half of Ig-like domain III is encoded by exon IIIa yielding a secreted receptor that is devoid of any signaling capacity. In case exon IIIa is spliced to either exon IIIb or IIIc, transmembrane receptors are formed. The expression of the IIIb variants is believed to be restricted to epithelial cell types, whereas the expression of the IIIc variants, especially in the case of FGFR-2 and FGFR-3, is believed to be restricted to mesenchymal cell types.

FGF binding results in receptor oligomerization, activation of the cytoplasmic tyrosine kinase domains, and receptor autophosphorylation. Intracellular signaling is then mediated through the tyrosine phosphorylation of key substrates and the activation of downstream pathways such as the mitogen-activated protein kinases (MAPKs) extracellular signal regulated kinase 1 (ERK-1) and ERK-2 (Figure 3). The existence of at least 18 human FGF ligands, four transmembrane FGFRs including a tyrosine kinase domain, and multiple FGF isoforms and FGFR splice variants can potentially result in a large combinatorial set of interactions. This further increases the complexity, diversity, and functional specificity of FGFs.

Figure 2 Schematic diagram of structural features of FGF receptors. FGFRs are usually composed of three extracellular immunoglobulin (Ig)-like domains (I–III), including a stretch of acidic residues (acidic box) unique for FGFRs, a hydrophobic transmembrane region followed by a juxtamembrane, and a split tyrosine kinase catalytic domain. The IIIa isoform is devoid of any signaling capacity. In the case of the IIIc isoform the second half of the Ig-like domain III (solid) corresponds to the exon 7 sequence of the *FGFR-1* gene, and in the case of IIIb the second half of the Ig domain III (open) corresponds to the exon 6 sequence of the *Fgfr1* gene.

Physiologic Actions

The expression of FGFRs seems to be fundamental for many processes, including limb, craniofacial, and lung development, hepatogenesis, osteogenesis, and inner ear formation. Mutations of *Fgfr1-3* genes have been linked to syndromes characterized by specific craniofacial and limb malformations. For example, mutations of *Fgfr2* were found in patients with Apert syndrome and mutations of *Fgfr3* in patients with achondroplasia.

FGF Actions in Cancer

Many studies demonstrate that alterations of the expression of FGFs and FGFRs play an important role in the development and progression of various malignant diseases. It is now well established that overexpression of FGFs can induce carcinogenesis through autocrine and paracrine mechanisms. The FGFR-mediated MAPK pathway is an important inducer of growth and has been implicated in tumor cell proliferation. By contrast, tumor-suppressive roles were described for FGFR1-IIIb and FGFR2-IIIb in the pancreas and prostate. FGFs can also regulate tumor cell survival pathways by increasing the expression of anti-apoptotic proteins such as XIAP and Bcl-X_L and triggering chemoresistance. Overexpression of FGFs was also associated with invasion and metastasis in a variety of human tumors. Tumor–stroma interactions are also of essential importance for tumor growth and extent of metastasis in several malignancies. Normal homeostasis of many organs depends upon the communication of epithelial and stromal compartments. This bidirectional signaling is mediated and controlled by multiple FGFs. In the case of the development of a malignant disease, specific ligands may gain growth-promoting functions by the expression of an FGFR variant

Figure 3 Schematic diagram of intracellular FGF signaling. FGF binding between Ig domain II and III results in receptor oligomerization, activation of the split cytoplasmic tyrosine kinase domains (rectangles) and receptor autophosphorylation. This is followed by binding, phosphorylation, and activation of fibroblast growth factor receptor substrate-2 (FRS2) or phospholipase C- γ (PLC- γ), which binds to tyrosine residue 766. Activation of the downstream mitogen-activated protein kinases (MAPK) extracellular signal regulated kinase -1 (ERK-1) and ERK-2 can occur via FRS2 or bypassing FRS2 and includes the signaling molecules Shc, Grb-2, SOS, ras, and raf.

usually not expressed in normal cells of the same origin. For example, human pancreatic stellate cells are able to induce FGFR1-IIIc and inhibit FGFR1-IIId expression in human pancreatic cancer cells, thereby enhancing the malignant phenotype. FGF-FGFR pathways are also involved in the regulation of epithelial-mesenchymal transition (EMT). EMT is a process where epithelial cells acquire properties of a motile and invasive mesenchymal-like phenotype. Epithelial cell characteristics are altered during EMT with changes in the expression of extracellular matrix proteins, proteins involved in cell adhesion and cell-cell interactions playing crucial roles in cancer progression and metastasis. FGF signaling also has direct effects on tumor angiogenesis by promoting cell proliferation in FGFR-expressing endothelial cells. Moreover, FGFs and other proangiogenic factors have also been implicated in the emerging phenomenon of resistance to vascular endothelial growth factor receptor-2 (VEGFR-2) inhibition.

FGF-2

FGF-2 exerts mitogenic effects on various endothelial, mesothelial, and epithelial cell types. It is overexpressed in a great portion of human tumor cell lines and various human malignancies. High levels of FGF-2 in serum of patients or in tumor specimens have been correlated with advanced tumor stage and poor prognosis in several gastrointestinal and other cancers, including thyroid, lung, and renal cell cancer. However, FGF-2 expression may be associated with favorable prognosis in ovarian and breast cancer.

FGF-1

FGF-1 is also a potent mitogenic factor for many normal and malignant cells and also expressed in a variety of cultured cell

lines and tissues. However, despite the fact that FGF-1 is present in many malignancies and can display similar biological activities as FGF-2, FGF-1 expression has not been clearly demonstrated to correlate with clinico-pathological parameters in human cancers.

FGF-3

The *Fgf3* gene was initially identified as murine mammary tumor virus integration site oncogene homolog (*int2*) implicated in mouse mammary tumors. *Fgf3* is localized on chromosome 11q13, a locus frequently amplified in malignant diseases. Amplification of *Fgf3* was associated with poor prognosis in breast cancer and biological aggressiveness in ovarian and esophageal cancer. The overexpression of FGF-3 in normal mouse mammary cells resulted in the development of orthotopically implanted tumors in nude mice, emphasizing the important role of FGF-3 in mammary tumorigenesis.

FGF-4

Testing the capacity of DNA from stomach tissues for their malignant transformation of fibroblasts resulted in the identification of *Fgf4*, also called *human stomach cancer transforming factor-1* (*hst-1*). The same oncogene was isolated by transfection of Kaposi sarcoma DNA and is therefore also called *kaposi sarcoma Fgf* (*kFgf*). *Fgf4* is also located on chromosome 11q13 together with *Fgf3*. Amplification of *Fgf4* correlates with increased risk of systemic recurrence after resection of esophageal cancer and with nodal involvement in head and neck cancers. FGF-4 overexpression increases the metastatic potential of breast cancer cells in association with altered expression of matrix metallo-proteinases.

FGF-5

Fgf-5 was also initially identified as a transforming proto-oncogene. The effectively secreted FGF-5 is produced by stromal cells (fibroblasts and pancreatic stellate cells) and acts primarily via FGFR-1 IIIc. FGF-5 is also expressed in breast cancer, several cancers of the gastrointestinal and urinary tract, and in glioblastoma multiforme. FGF5 can contribute to the malignant progression of human astrocytic brain tumors and pancreatic cancer by both autocrine and paracrine effects.

FGF-6

FGF-6 or human stomach transforming factor-2 also displays transforming potential and was found in prostate cancer in conjunction with FGFR-4. Exogenous FGF-6 enhances the proliferation of primary prostatic epithelial and stromal cells and prostate cancer cell lines, suggesting that FGF-6 may act as paracrine and autocrine factor in prostate cancer.

FGF-7

FGF-7 is an important mitogen for a variety of epithelial and cancer cells, including liver, pancreas, gastrointestinal tract, lung, and breast. Inhibition of FGF-7 signaling results in reduced mobility and invasion of breast and gastric cancer cells. FGF-7 is overexpressed in many cancers, but is expressed at lower levels in squamous cell carcinomas of the head and neck and endometrial cancers by comparison with the corresponding normal tissue. A similar observation has been made for serum levels of FGF-7, which were lower in patients with prostate cancer in comparison to patients with benign prostatic hyperplasia. Together, these observations suggest that FGF-7 may localize in different cell types within these pathological tissues and may differentially modulate tumor growth depending on the expression and localization of the FGF receptors in these tissues.

FGF-8

FGF-8 or androgen-induced growth factor was isolated from SC-3 androgen-stimulated mouse mammary carcinoma cells and found to be overexpressed in breast cancer. *Fgf-8* has been proposed to enhance murine mammary tumorigenesis in cooperation with the *Wnt-1* proto-oncogene. It was found that the four known human FGF-8 isoforms (a, b, e, and f) display different proliferating and transforming potencies, the FGF-8b isoform being the most potent. Thus, constitutive expression of FGF-8b resulted in enhanced invasion, angiogenic capacity, and tumor growth of breast cancer cells. FGF-8b initiated prostatic intraepithelial neoplasia and prostate cancer when expressed in a *Pten* haplosufficient background, underscoring its potential role for these malignancies.

FGF-9 to -23

Expression of FGF-9 or glia-activating factor, FGF-10, and FGF-19 was detected in various cancer tissues. These FGFs are also able to act as mitogens. Thus, FGF-10 was able to induce by autocrine and paracrine mechanisms pulmonary and prostate cancers. FGF-19 transgenic mice that overexpressed FGF-19 in skeletal muscle exhibited elevated hepatic α -fetoprotein levels at 2 months of age and developed hepatocellular

carcinomas by 10 months of age. In this context, the effects of FGF-19 are hormonal. The effects of FGF-19 on the development of hepatocellular carcinomas are mediated almost exclusively via FGFR-4.

FGFR Actions in Cancer

Aberrant FGF signaling in cancer underlies tumor-specific mechanisms. They can be divided into genomic FGFR alterations responsible for ligand-independent receptor signaling and into changes in receptor isoform expression supporting ligand-dependent activation. The ligand-dependent signaling has a similarly important role in the pathogenesis of cancer, by either autocrine or paracrine production of ligands from cancer or stromal cells, respectively.

FGFR-1

FGFR-1 is expressed in a wide variety of cell types and tissues, including many malignancies. Amplification of the *Fgfr1* locus on chromosome 8p12 is one of the most common focal amplifications in breast cancer (~10%), predominantly in estrogen-receptor-positive cancers. It was also reported in oral squamous carcinoma, ovarian and bladder cancer, and rhabdomyosarcoma and is associated with nodal involvement in breast cancer and poor prognosis of patients with bladder cancer. An atypical stem-cell myeloproliferative disorder evolving toward acute myelogenous leukemia is characterized by a 8p12–p11 breakpoint and a t(8;13) translocation resulting in an aberrant formation of a tyrosine kinase with the catalytic domain of FGFR-1 and constitutive kinase activity. This translocation was also found in breast cancer. Expression of *Fgfr1* in transgenic mice suggests that FGFR-1 plays an important role in mammary gland tumorigenesis. Deletions of 8p12 have been reported for choriocarcinoma, and frequent disturbances, including amplification or deletions, have been reported in prostate cancer. Overexpression of wild-type FGFR1 was also reported in cancer. FGFR-1 expression can be induced by overexpression of cyclin D1 in fibroblasts via the pRb/E2F pathway. Cyclin D1 is known to be overexpressed in many malignancies and correlates with poor prognosis in several malignancies. Recent evidence also suggests that N-cadherin expression can enhance tumorigenesis via FGFR-1. FGFR-1 ligand-induced internalization was reduced by N-cadherin mediated by the first two Ig-like domains and resulted in increased FGFR-1 stability and sustained activation of MAPK.

A potent ligand of FGFR-1, FGF-2, has been shown to be an important prognostic factor for many malignancies. Nevertheless, high FGFR-1 expression was only associated with poor differentiation in prostate cancer, advanced stage in head and neck squamous cell carcinoma, and nonsmall cell lung cancer. In addition, recent evidence suggests that alterations in the expression of certain splice variants may be responsible for malignant transformation. Thus, expression of FGFR-1 IIIc in normal ductal pancreatic epithelial cells resulted in the establishment of an autocrine loop and cellular transformation with increased proliferation and *in vivo* tumor formation. Expression of FGFR-1 IIIc in the cancer cells, which are of epithelial origin, has been linked to the pathogenesis of pancreatic and

prostate cancers. Additionally, altered expression of FGFR-1 splice variants has been reported for breast cancer. Especially, the 2-Ig-like isoform (also called FGFR-1 β) is upregulated in pancreatic, prostate, and breast cancers, and in astrocytomas and glioblastomas in comparison to the 3-Ig form (FGFR-1 α). More recent data suggest that besides enhancing proliferation, FGFR1 signaling can initiate cancer development and promote invasion and metastasis.

Inhibition of FGFR-1 signaling using dominant-negative or soluble forms of the receptor resulted in significant growth inhibition in pancreatic, breast, prostate, and several other cancer cell lines. Using vaccination with *Xenopus* FGFR-1 in a murine tumor model resulted in the production of FGFR-1-specific auto-antibodies and effective anti-tumor activity and suppression of angiogenesis. By contrast, over-/re-expression of FGFR1-IIIb in ductal pancreatic cancer cells resulted in the reversion of the malignant phenotype, also pointing to tumor suppressive effects of FGF-FGFR pathways in cancer. Recent studies in pancreatic cancer about the expression of the tumorigenic FGFR1-IIIc isoform and the tumor-suppressive FGFR1-IIIb isoform revealed that several growth factors can induce IIIc expression via cyclin D1 and inhibit IIIb expression. Tumor-suppressive functions of FGFR1-IIIb were associated with increased expression of osteonectin, a matricellular glycoprotein important for cell-cell contact and proliferation. The change from FGFR1-IIIb to FGFR1-IIIc expression in pancreatic cancer may also be a result of the EMT similar to FGFR-2 in prostate cancer.

FGFR-2

FGFR-2 is also found in a wide variety of cell types and tissues and was first identified as an amplified gene from a human gastric cancer cell line. Amplification of *Fgfr2* on chromosome 10q26 is observed in about 10% of gastric cancers and also in breast and oral squamous cell carcinomas. One important isoform, keratinocyte growth factor (KGFR), is devoid of the Ig-like domain I and the acidic box and contains sequences encoding the IIIb variant. Overexpression of KGFR occurs in gastric and pancreatic cancers, and is associated with poor differentiation in prostate cancer and poor prognosis in pancreatic cancer, whereas KGFR expression is lower in endometrial cancer in comparison to the normal endometrium.

An essential feature of *Fgfr2* is its proposed strictly tissue-specific expression using exon IIIb in epithelial cells and IIIc in mesenchymal cells. Exon switching from IIIb to IIIc in conjunction with the presence of stromal cell-derived FGF-7 was accompanied with malignant progression in a prostate cancer model, downregulation of IIIb with malignant progression of the prostate, and de-differentiation of normal oral keratinocytes into a malignant phenotype. This exon switch from FGFR-2 IIIb to FGFR-2 IIIc can be induced by the presence of FGF-1 and -2 in keratinocytes, fibroblasts, and bladder carcinoma cells. Re-expression of KGFR by transfection, in human salivary gland adenocarcinoma cells which lost KGFR expression in the process of malignant transformation, resulted in growth inhibition, induction of differentiation, and apoptosis. *Fgfr2* mutations linked to craniosynostosis syndromes and resulting in constitutive receptor activation with transforming potential were also detected in endometrial and gastric cancers,

suggesting also that gain-of-function mutations of *Fgfr2* can play a role in tumorigenesis.

FGFR-3

Mutations of *Fgfr3* were identified in a great portion of bladder carcinomas and at low frequency in cervical, urothelial cell, prostate, and colorectal carcinomas, multiple myeloma, and seminomas. Many of these mutations occurred at highly conserved sequences in the Ig-like domain III, highlighting the functional importance of this domain. Interestingly, the presence of FGFR-3 mutations in bladder and urothelial cell carcinoma was associated with better outcome. Amplifications of *Fgfr3* in cancer are rare events.

Nuclear accumulation of FGFR-3 has been reported for breast cancer. This is probably related to a splice variant in which exons 7 and 8 are deleted resulting in the translation of a soluble intracellular FGFR-3 missing the transmembrane domain, but with an intact kinase domain. Using other splice variants that are devoid of the acidic box, it could be shown that inhibitory functions of FGFR-3 can be abolished. Other variants with altered ligand-binding specificities were described in osteosarcoma and squamous carcinoma cell lines. Thus, depending on the mutations and the receptor splice variant expressed, FGFR-3 can display transforming potential, supporting the possible role of FGFR-3 in the pathogenesis of some malignancies. Moreover, *Fgfr3* translocations have been described for hematological malignancies.

FGFR-4

A G to A conversion resulting in a substitution of glycine by arginine at position 388 in the transmembrane domain of the *Fgfr4* gene has been described. Expression of this receptor in mammary tumor cells increased cell mobility and the presence of this allele was associated with lymph node metastases and more advanced disease in colon cancer and reduced disease-free survival in breast cancer. Blocking FGF19 antibodies further suggested that proliferation of colon cancer cells may be driven by an autocrine loop involving FGFR4. Amplification of *Fgfr4* on 5q35.1-qter has been described for some breast and ovarian cancers, leukemias, and lymphomas. FGFR-4 overexpression was reported in endocrine tumors of the digestive system, several gastrointestinal and urinary tract cancers as well as breast and lung cancers. FGFR-4 has also been correlated with low differentiation and tends to be associated with shorter patient survival in astrocytomas.

Furthermore, a truncated form of FGFR-4 lacking the first two Ig-like domains was identified in human pituitary tumors. Because the N-terminus of this truncated receptor lacks a signal peptide, it is not inserted into the plasma membrane and resides in the cytoplasm. The truncated receptor is constitutively phosphorylated and exhibits transforming potential in fibroblasts. Its expression in transgenic mice results in the formation of pituitary tumors suggesting that this isoform may play an important role for the development of pituitary tumors. Experiments using dominant-negative FGFR-4 also suggest that FGFR-4 may be involved in matrix adhesion and, therefore, tumor dissemination. Expression of FGFR-4 induced membrane ruffling, a sign of transformation of breast cells, in

the presence of FGF-1 or -2. Furthermore, differentiation of teratocarcinoma cells was associated with loss of FGFR-4 expression.

Summary

Besides their involvement in many biological processes during development and in the adult, FGFs and FGFRs are involved in the pathobiology of many malignancies. One important reason for this role seems to be the altered expression of FGFs and FGFRs and their isoforms resulting in the aberrant activation of autocrine and paracrine signaling loops that eventually promote tumorigenesis. Other changes include the expression of abnormal FGFs or FGFRs with constitutive activation of FGFR tyrosine kinase signaling. Thus, the discovery and functional analysis of the role of FGF–FGFR alterations in specific cancer entities and other malignancies may result in the treatment

strategies in the future targeting these pathways or using these pathways for specific treatment.

Glossary

Fatty acyl-CoA Derivatives of fatty acids (CoA thioesters) formed in cells to initiate oxidation of the fatty acid.

Glyoxisome/peroxisome Common membrane-enclosed compartments in plant and animal cells.

Hydroperoxide A derivative of hydrogen peroxide where one of the H atoms is replaced by a chemical group.

Isoalloxazine Fused three-ring structure that forms the core chemical function of flavins.

Redox Shorthand for reduction and oxidation processes.

The word flavin in biochemistry comes from the Latin word meaning yellow. The root word flavin was used in the early twentieth century to refer to yellow compounds extracted from tissue samples. Richard Kuhn is credited with the preparation of pure riboflavin (which he called lactoflavin – from milk) and its structural determination. Kuhn received the Nobel prize for this and other work in 1938. Today, the term ‘flavin’ is reserved for a group of compounds that contain the fused three-ring structure called isoalloxazine, which is responsible for the yellow color.

The most important flavins in nature are riboflavin, flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD) as shown in [Figure 1](#). Riboflavin is often known as vitamin B2 (one of the soluble vitamins), which is an essential requirement in the diet of mammals and many other organisms. Riboflavin is manufactured by most microorganisms and plants. There is now a great deal of information on the process of biosynthesis. Organisms that require riboflavin as a vitamin use specific enzymes and adenosine triphosphate (ATP) to convert the compound into both FMN and FAD. These nucleotides are used as cofactors (or prosthetic groups) in the structure and function of many proteins. The relationship with proteins is so important that we normally think of flavins in the context of protein structures. Thus, we refer constantly to flavoproteins as proteins with a flavin cofactor. This article describes the fundamentally important functions of these compounds in a wide variety of chemical processes in nature.

Chemistry

The chemistry of flavins has been studied extensively. Riboflavin is a stable compound with a variety of interesting properties. FMN and FAD are much more important in cells, but are less stable in solution because of the presence of phosphate ester and anhydride bonds. The isoalloxazine is responsible for the important biological chemistry of all flavins. Only the reactions most relevant to life are mentioned below. One reason that flavoproteins have been so extensively analyzed is that they can be studied by examining the properties of their cofactor that is nearly always involved in the core function of each protein. Another reason is the variety of chemical properties that have been exploited for important biological functions of considerable diversity.

Redox Properties

Oxidized flavins (called flavoquinones) can be reduced by the addition of two electrons and two protons, and the redox potential for reduction is -0.2 V at pH 7 ([Figure 2](#)). Reduced flavins (flavohydroquinones) are thus moderate reducing agents and can occur as either a neutral or an anionic form. Part of the versatility of flavins comes from their ability to be reduced in one-electron steps because flavins are capable of forming stable free radicals (flavosemiquinones in [Figure 2](#)). A neutral and an anionic free radical can be formed by flavins, and both occur in nature. Proteins modify these redox properties by the interactions formed with the flavin cofactor to enable a wide variety of biological processes. Flavins can pass electrons to transition metal ions. Many proteins make use of this property to link stable reducing compounds (e.g., NADH) to reactive metal ions and one-electron processes in electron transport chains. Flavins are almost always involved as the transforming molecule for linking two-electron to one-electron processes.

Oxygen and Other Derivatives

Flavins, unlike most organic molecules, react with oxygen. This reactivity is a product of the redox properties mentioned above. Oxygen is unreactive unless free radical intermediates are formed. Reduced flavins provide the capacity for one-electron reductions and, in addition, have the ability to form reactive covalent adducts with oxygen and other molecules. Bruice and colleagues have shown that the reactions between reduced flavins and oxygen involve covalent adducts and free-radical intermediates. Many proteins take advantage of the oxygen adducts ([Figure 3](#)) to help carry out chemical reactions. A wide variety of biological processes depend upon the specific interactions between particular proteins and these flavin adducts. A small number of proteins form stable covalent bonds to the flavin through the 8- and/or the 6-positions ([Figure 1](#)).

Spectroscopic Properties

Oxidized flavins (the stable form) are normally yellow due to a major electronic transition observed at 450 nm ([Figure 4](#)). Full reduction of flavins (two equivalents) gives a structure that has

Figure 1 The structures of flavins discussed in this article. The numbering system shown for the isoalloxazine ring is used in the text.

a low absorbance beyond 400 nm, and is almost colorless (pale yellow) by comparison to oxidized flavins. Free-radical flavins (flavosemiquinones) have complex spectra with spectacular colors – either red or blue (**Figure 4**), depending on the state of protonation. Flavins also form charge-transfer complexes with a variety of other compounds. These complexes have a range of different visible spectra with a corresponding variety of colors. Such complexes generally have weak absorbance bands between 500 and 800 nm. Various proteins can stabilize one or more of these chemical species, so that flavo-proteins can have many colors, besides changing color during catalytic function.

Flavins have important luminescent spectral properties. Many flavins are fluorescent, and the fluorescence properties are strongly influenced by association with proteins and by the oxidation state or formation of derivatives. These properties can be studied in biological systems because the flavin can be excited by light (between 350 and 480 nm) and the emitted light is a broadband with a peak near 530 nm. This property provides a sensitive assay of flavins down to 10^{-9} M. The

Figure 3 The structure of transient oxygen derivatives of the isoalloxazine ring that are important in protein function. Note that thiol groups can form a similar structure to the C4a-hydroxide. The biological function of the sulfur derivative is discussed in this article.

Figure 4 Absorption spectra of the redox states of FAD in glucose oxidase. A solution of 9.5 μM oxidized enzyme (solid line/open circles) was photoreduced in anaerobic conditions at pH 9.2 to form the red, anionic semiquinone. The solution was shifted to pH 5.0 with citric acid to form the blue semiquinone, and then reduced with glucose to form the hydroquinone (solid line/open squares).

fluorescent properties of flavoproteins often provide information not available from absorbance properties. Flavins can even be trapped in excited states and this has been exploited in living systems. Nature has also utilized the enhanced reactivity of the excited states of flavins that last long enough to be chemically useful. For example, the 4a-hydroxyflavin is often fluorescent, whereas the hydroperoxyflavin is not, even though they have nearly identical absorbance spectra.

Types of Flavoproteins

To try to display the diversity and utility of flavin function in living systems, we adapt below the classification system for flavoproteins developed by Massey.

Pyridine Nucleotide Oxidoreductases

There is a diverse group of proteins that connects the stable reducing currency of cells (NADH/NADPH) with other redox processes required for cellular function. For example, glutathione reductase is one of a group of related disulfide reductases that contain both FAD and a pair of reactive cysteine residues in the active site. The function of this enzyme is to help maintain a reducing environment within cells by keeping glutathione reduced. Glutathione then carries out many important functions such as reducing disulfides in proteins and removing hydrogen peroxide from cells (catalyzed by glutathione peroxidase). Through the flavin buried in the protein, the enzyme can use the reducing power of NADPH to reduce the disulfide of glutathione, because the flavin reacts rapidly with thiols

by the formation of a transient covalent adduct (Figure 3). Another example is ferredoxin reductase, the enzyme principally associated with photosynthesis that enables reactive, strongly reducing proteins such as ferredoxin to provide stable reducing equivalents in the cell as NADPH. Through the FAD in the active site, the enzyme can accept single reducing electrons from ferredoxin (electrons collected from the reactive free-radical photochemical process) that can then be safely stored as NADPH.

Dehydrogenase/Electron Transferase

There are a limited number of enzymes that use flavins to link oxidation of a stable metabolite to electron transport chains for energy conservation in cells. For example, succinate dehydrogenase is a component of the citric acid cycle in mitochondria and it links directly into the respiratory complexes through an iron/sulfur cluster complex. The FAD in this enzyme is covalently linked to the protein where it accepts a pair of electrons from the oxidation of succinate and then transfers single electrons into the respiratory complex II. The acyl-CoA dehydrogenases in animals have a similar fundamental role in obtaining energy from the oxidation of fats. These enzymes contain FAD, which accepts electrons and the latter accepts electrons from a fatty acyl-CoA to initiate oxidation of a fatty acid. In this case, the electrons are transferred to the respiratory chain in mitochondria through another soluble flavoprotein called the electron transferring flavoprotein. In plants, the process of fatty acyl-CoA oxidation occurs in glyoxisomes (rather than mitochondria) by the use of similar enzymes that are oxidases. That is, after being reduced by the fatty acyl-CoA, the enzyme flavin reacts with oxygen to dispose of the reducing electrons. The difference between these enzymes in animals and plants is a subtle change in the protein interactions with the FAD that changes the course of the reaction.

Electron-Transfer Proteins

There is a small group of proteins that act to provide single reactive reducing electrons for a variety of biological reactions. Most of these proteins contain iron/sulfur complexes, but a few are flavoproteins that use the ability of flavins to form stable free radicals. For example, flavodoxins are widespread in microorganisms and have been extensively studied. The protein in flavodoxins makes a specific interaction with the isoalloxazine ring that stabilizes the blue neutral radical (Figures 2 and 4), and makes further reduction difficult. Thus, when reduced, flavodoxins are strong one-electron reducing agents. Electron-transferring flavoprotein referred to earlier is a different member of this family of proteins.

Oxygenases

Flavins are widely employed in cells to unlock the reactivity of the oxygen molecule. Oxygenases not only react with oxygen, but also incorporate oxygen into metabolites. There are

many types of flavoprotein oxygenases that tame oxygen for useful purposes. For example, *p*-hydroxybenzoate hydroxylase adds one atom of oxygen to an aromatic ring so that it can eventually be used for carbon and energy supply for a microorganism. Oxygenated aromatic rings are then converted to aliphatic compounds by subsequent metabolic steps. *p*-Hydroxybenzoate hydroxylase contains FAD in the structure and has been studied extensively to understand this type of reaction. In catalysis, the reduction of FAD by NADPH is tightly controlled in a remarkable process. The enzyme senses the presence of the substrate *p*-hydroxybenzoate in the active site and responds by swinging the isoalloxazine ring to the surface of the protein where it contacts the NADPH. This process makes use of the flexibility of the ribityl side chain of FAD. Then, after reduction, the isoalloxazine swings back into the interior of the protein where it forms a transient covalent adduct (Figure 3, hydroperoxide) in the controlled environment of the enzyme. The peroxide provides the reactive oxygen to oxygenate the substrate. Cyclohexanone monooxygenase provides a different example where the FAD, after reduction by NADPH, reacts with oxygen to form a peroxide anion that reacts rapidly with the carbonyl group of cyclohexanone. Another variation is found in lactate monooxygenase. Here, the enzyme flavin (FMN) is reduced by the substrate lactate to form pyruvate that is held by the enzyme and oxygenated by the peroxide formed from the reaction between reduced FMN and oxygen.

Oxidases

Flavoproteins can also use oxygen as a sink for removing unwanted reducing electrons. This process was briefly referred to above in relation to fatty acyl-CoA oxidase in plants. Another important example is glycolate oxidase in plants. During photosynthesis, glycolate is formed as an unwanted byproduct and must be removed. Glycolate oxidase uses FMN to oxidize glycolate to glyoxalate, which is then aminated to form glycine, a normal amino acid. This process occurs in peroxisomes where oxygen is used to react with reduced FMN to remove the reducing electrons from glycolate, rather than through an electron transport chain. The oxygen is reduced to hydrogen peroxide (similar to the oxygenases), but the peroxide is released from the enzyme and must be removed from the cell by other enzymes such as catalase to prevent dangerous side reactions. Other examples of this use of oxygen by flavoproteins are amino acid oxidases in kidneys and glucose oxidase in fungi. It is the absence of a flavoprotein oxidase function (gulonolactone oxidase) that explains why humans require vitamin C in their diets, when most animals can make this molecule. In humans, the gene for this enzyme has mutated and no longer codes for a functional protein.

Photochemistry

Flavoproteins show some really novel functions when the properties of their excited states are utilized in cells. A classic example is bacterial luciferase, which is an enzyme that

produces lime-green light from chemical energy. The light-producing process is an outgrowth of the reactions of the oxygenases. NADH is used to reduce FMN by one enzyme and then the reduced FMN binds to luciferase where it reacts with oxygen to form the flavin C4a-hydroperoxide (Figure 3). The novel reaction occurs when the hydroperoxide oxidizes a fatty aldehyde to form the corresponding fatty acid. In this reaction, the protein traps the FMN in an excited state of the flavin C4a-hydroxide (Figure 3), which can decay with the release of a photon. Many marine animals in the deep oceans form symbiotic relationships with the bacteria that make luciferase. The animal can then form light-emitting organs essential for communication, hunting, or defense.

Just as remarkable as luciferase is DNA photolyase, which is found in all cells. An essential part of cellular survival is the maintenance of the integrity of genetic information in the face of damage by environmental factors. One source of damage is UV light, which can cause cross-linking of bases in the DNA helix. It is the task of DNA photolyase to repair the damage often by using the same source of light that caused the damage. This enzyme contains both an FAD and an accessory pigment. The flavin functions in the protein in the reduced state, where it is converted to a powerful reducing agent when excited by energy from light. The excited reduced state is powerful enough to break down the unwanted covalent bonds in damaged DNA and thus repair the integrity of the genetic information. Electrons used for this purpose are then recovered to reform the reduced FAD.

Another developing story about flavoprotein photochemistry involves flavins as blue-light photoreceptors. For example, phototropins are photoreceptors for some plant responses to light. These proteins contain FMN that forms a transient and reversible covalent bond to an active site cysteine upon illumination. This complex is thought to form through a free-radical mechanism of excited state flavin chemistry. In addition to these, cryptochromes are flavoproteins similar in structure to DNA photolyase (above), and they provide modulation of circadian rhythms in animals upon irradiation with blue light.

Medical Significance

It is extremely rare for riboflavin deficiency to occur in humans because of its widespread occurrence in food. However, some flavoproteins are important in medical practice. A few examples are mentioned below.

A common medication for gout (caused by excess uric acid) is allopurinol. This drug inhibits xanthine oxidase, a complex flavoprotein involved in the formation of the uric acid that causes gout. Uric acid is the end product of the natural breakdown of purines in the body.

Another complex flavoprotein, monoamine oxidase, is present as two different proteins in the nervous system. Both are targets for modulation by drug therapy, particularly for depression, because this enzyme degrades some of the potent natural neurotransmitters involved in mental disorders.

The flavoprotein, methylenetetrahydrofolate reductase, is involved in the formation of the amino acid methionine. About 12% of the human population has a form of the enzyme

that leads to elevated homocysteine in the blood, a major risk factor in cardiovascular disease.

Some medications for stomach ulcers work because they are substrates for the bacterial flavoprotein, nitroreductase, produced by the ulcer-causing *Helicobacter pylori*. The reduced products formed from the drug by the enzyme kill the bacterial cells.

Flippases

C J Waechter, University of Kentucky College of Medicine, Lexington, KY, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Dolichyl monophosphate An eukaryotic glycosyl carrier lipid containing 15–20 isoprene units in which the α -isoprene unit is saturated.

Flippase A general term for a class of membrane proteins proposed to facilitate the transbilayer movement of the polar headgroup of a phospholipid, glycosphingolipid, or a polyisoprenyl-P(-P)-linked glycosyl intermediate.

Scramblase Bidirectional, adenosine triphosphate (ATP)-independent transporters that randomly redistribute polar

lipids formed *de novo* in the endoplasmic reticulum. This class also facilitates the nonspecific, bidirectional movement of phospholipids in the plasma membrane.

Transverse diffusion The flip-flopping or transbilayer movement of a polar membrane lipid from one leaflet to the opposite monolayer of a cellular membrane.

Undecaprenyl phosphate A fully unsaturated bacterial glycosyl carrier lipid containing 11 isoprene units.

Introduction

During the bioassembly of N-linked oligosaccharides, C- and O-linked mannosyl units in proteins, glycosylphosphatidylinositol (GPI) anchors, glycosphingolipids, and newly formed phospholipid bilayers in eukaryotic cells, charged hydrophilic headgroups must diffuse transversely through the hydrophobic core of the endoplasmic reticulum (ER) and an early Golgi compartment. Similarly, in prokaryotes, phospholipids and undecaprenyl pyrophosphate-linked glycosyl building blocks must be translocated from the inner leaflet to the outer monolayer during the expansion of the cytoplasmic membrane and the biosynthesis of cell-wall components. Biochemical and biophysical model systems indicate that the unassisted transbilayer movement of polar lipids with charged headgroups is highly unfavorable thermodynamically and much too slow to allow cells to synthesize the essential glycoconjugates in a physiologically requisite time frame. Thus, it has been proposed that the flip-flopping of the amphipathic precursors/intermediates is mediated by a class of membrane proteins referred to as flippases. The term flippase was originally suggested by Mark Bretscher during the 1970s.

Three types of the transbilayer movement of lipids with the generalized structure of glycerophospholipids and of the glycolipid intermediate, mannosylphosphoryldolichol (Man-P-Dol), mediated by flippases are illustrated in [Figures 1](#) and [2](#). [Table 1](#) summarizes several examples of polar lipids whose transverse diffusion is believed to be facilitated by flippases in prokaryotic and eukaryotic cells. Despite the critical function of flippases in membrane biology, there are still very large gaps in the information about their structures, the genes encoding this vital class of proteins, and the mechanism(s) by which they shield and permit the passage of the polar moieties through the hydrophobic core of the ER and other cellular membranes.

during active membrane biogenesis, ~50% of the newly formed phospholipids must be translocated to the lumenal monolayer. The landmark study of Kornberg and McConnell proved that the unassisted movement of spin-labeled phosphatidylcholine (PC) molecules between the two leaflets of pure lipid vesicles did not occur fast enough to maintain bilayer expansion at physiological rates. Further emphasizing the essential role of flippases, the classic experiments of James Rothman and Eugene Kennedy demonstrated that movement of phosphatidylethanolamine molecules, newly synthesized on the cytoplasmic leaflet of a *Bacillus megaterium* cell, to the extracellular monolayer was remarkably faster than the rate of spontaneous diffusion in artificial lipid bilayers. Primarily due to severe technical difficulties inherent in studying the phospholipid flippase(s), there is still very little known about the structure and mechanism of this eminently important class of membrane proteins. Bishop and Bell proposed the novel idea of following the transport of a water-soluble analog (diC₄PC) of PC by sealed microsomal vesicles to implicate one or more ER proteins in the transbilayer movement of the major membrane phospholipid. The PC flippase is depicted in [Figure 1\(a\)](#). The basic principle of this experimental approach is to design a water-soluble form of the polar lipid in which the hydrophobic groups are reduced in size to increase their solubility in aqueous solutions while retaining the essential structural features recognized by the proteins mediating their translocation. Although this experimental approach and alternate methods have been utilized by other researchers more recently to make progress toward these goals, the PC and other phospholipid flippases in biogenic membranes remain to be identified, isolated, and cloned. Neutral lipids such as cholesterol, coenzyme Q, and neutral glycerides may diffuse transversely in cellular membranes by a protein-unassisted process because they lack charged, hydrophilic groups.

Expansion of the ER Bilayer during Membrane Biogenesis

It is well established that the major site of phospholipid biosynthesis *de novo* in eukaryotes is on the cytoplasmic leaflet of the ER membrane. Clearly, to have uniform expansion of the bilayer

Aminophospholipid Flippases (P4-Adenosine Triphosphatase Family)/Translocases, Floppases, Scramblases, and Phospholipid Asymmetry

In most, if not all, cellular membranes phospholipids are distributed asymmetrically between the two leaflets, a property

Figure 1 Illustration of three types of flippase-mediated transbilayer movement of membrane phospholipids in the ER or Golgi. The transbilayer movement of phosphatidylcholine during membrane biogenesis in the ER (a); the ATP-dependent flip-flopping of phosphatidylserine/phosphatidylethanolamine from the outer surface to the inner leaflet of the plasma membrane (PM, C, left) by the P_4 -ATPase family/aminophospholipid flippases (b); and the bidirectional, ATP-independent, Ca^{2+} -activated movement of a polar lipid mediated by scramblases is depicted in model (c). Although the translocation in examples in (a) and (b) is illustrated as being unidirectional, these processes appear to be bidirectional.

that is critical to membrane function. Thus, in addition to the flippases crucial to uniform expansion of the bilayer in the ER during membrane biogenesis, another set of flippases is required to maintain the proper distribution of phospholipids between the two leaflets of membranes in the various cellular compartments. The combined action of aminophospholipid flippases (P_4 -adenosine triphosphatase (ATPase) family members), two types of outwardly driven floppases (multidrug resistance, MDR, P -glycoprotein, other members of the MDR family, and members of the multidrug resistance-associated protein, MRP, subfamily) and possibly the adenosine triphosphate (ATP)-independent, Ca^{2+} -activated, bidirectional scramblases (Figure 1(c)) are believed to play a role in the asymmetric distribution of PC and other membrane phospholipids between the two leaflets of the plasma membrane (PM) and other cellular membranes.

The best characterized of the candidate flippases is the ATP/ Mg^{2+} -dependent aminophospholipid flippase (P_4 -ATPase family). The properties of this type of flippase have been studied extensively, and progress has been made in purifying the protein component(s). It has been found in the PM of erythrocytes and other mammalian cells, synaptosomes, chromaffin granules, and secretory vesicles. This flippase appears to play a direct role in maintaining the enrichment of phosphatidylserine (PS) and phosphatidylethanolamine (PE) in the inner leaflet of the PM by moving the two aminophospholipids from the outer to the inner leaflet of the PM against a concentration gradient at the expense of ATP. In Figure 1(b) (left) the lipid moiety would be diacylglycerol and the polar headgroup (O) would be either phosphorylserine or phosphorylethanolamine. The loss of this activity due to diminishing ATP pools or the loss of the protein(s) allows PE/PS to diffuse back to the outer monolayer where the surface alteration is recognized by the immune system as an early signal in apoptosis.

Figure 2 Illustration of the transbilayer movement of mannose-P-dolichol in the ER of eukaryotic cells mediated by a putative flippase composed of one or more membrane proteins. Man-P-dolichol is an intermediate mannosyl donor in protein N-glycosylation, C- and O-mannosylation, as well as in GPI anchor assembly. The transbilayer movement of Glc-P-dolichol and $Man_5GlcNAc_2$ -P-P-dolichol, two other glycolipid intermediates in the biosynthesis of asparagine-linked oligosaccharides, in the ER is also proposed to be facilitated by flippases.

However, inhibition of the flippase or loss of ATP is insufficient to cause a rapid loss of PM PS asymmetry. Rapid PS externalization requires the additional activation of a (Ca^{2+} -dependent) scramblase. The bidirectional, ATP-independent, Ca^{2+} -activated scramblase (Figure 1(c)) plays an important role in platelet activation, blood clotting, and apoptosis.

There is good evidence that floppases mediate the ATP-dependent translocation of cholesterol, PC, and sphingolipids from the cytoplasmic to the external leaflet of the PM.

Protein N-Glycosylation

N-linked oligosaccharide chains are initially synthesized as the dolichyl pyrophosphate (Dol-P-P)-linked precursor oligosaccharide by a two-stage process in the ER. In the first stage, three lipid intermediates, mannosylphosphoryldolichol (Man-P-Dol), glucosylphosphoryldolichol (Glc-P-Dol), and a heptasaccharide intermediate ($Man_5GlcNAc_2$ -P-P-Dol) are synthesized in the ER by enzymes with active sites facing the cytoplasm. In the next stage, these three glycolipid intermediates diffuse transversely to the luminal monolayer where four more mannosyl units are added to $Man_5GlcNAc_2$ -P-P-Dol with Man-P-Dol (Figure 2) functioning as the mannosyl donor. Finally, three glucosyl units are donated by Glc-P-Dol, completing the synthesis of the oligosaccharyl donor, $Glc_3Man_9GlcNAc_2$ -P-P-Dol. Based on evidence obtained from biophysical and enzymological topological studies, it is very likely that the transverse diffusion of the three intermediates requires ER proteins functioning as flippases to maintain lipid intermediate biosynthesis and protein N-glycosylation at physiologically relevant rates. Evidence has been obtained for the presence of ER proteins that mediate the transbilayer movement of short-chain, water-soluble analogs of Man-P-Dol and Glc-P-Dol by sealed vesicles from rat liver and brain by a variation of the experimental approach pioneered by Bishop and Bell. Preliminary studies using this transport technique indicate that the flippases are bidirectional and ATP

Table 1 Summary of specific flip-flopping events in prokaryotic and eukaryotic cells

Polar lipid	Membrane site	Transbilayer movement from
Aminophospholipids (PS/PE)	Plasma membrane	Outer leaflet to inner monolayer
PC and other glycerophospholipids, GlcN-PI, Man-P-Dol, Glc-P-Dol, and Man ₅ GlcNAc ₂ -P-P-Dol	ER	Cytoplasmic to luminal leaflet
Glucosylceramide	Early Golgi	Cytoplasmic to luminal leaflet
Glycerophospholipids and undecaprenyl-P(P)-linked cell-wall intermediates	Bacterial cytoplasmic membrane	Cytoplasmic leaflet to exterior monolayer (or outer membrane)

independent. It is plausible that this class of flippase acts by facilitated diffusion, and the transbilayer movement of the lipid intermediates is driven by mass action as they are consumed during Glc₃Man₉GlcNAc₂-P-P-Dol synthesis on the luminal surface. Hopefully, the *in vitro* assays will provide a means to isolating the ER proteins involved in this flip-flop-ping process. More recently, genetic and biochemical studies have implicated the *Rft1* protein in the transbilayer movement of Man₅GlcNAc₂-P-P-Dol in the yeast, *Saccharomyces cerevisiae*, although the precise function of this protein has yet to be determined. The structure of the yeast protein mediating the flipping of Man₅GlcNAc₂-P-P-Dol may provide clues to the identity of the gene encoding the corresponding protein in mammalian cells. The identification of the flippase proteins involved in the dolichol pathway and the corresponding genes should also ultimately be relevant to the diagnosis of related genetic defects in patients with as-yet uncharacterized forms of congenital disorders of glycosylation.

Relationship of a Man-P-Dol Flippase to the Biosynthesis of Other Mannose-Containing Glycoconjugates

Protein O- and C-Mannosylation

In yeast and mammalian cells, many proteins are modified by the addition of mannosyl units from Man-P-Dol to either serine/threonine in O-mannosidic linkage or to the indole ring of tryptophan residues in a C-mannosidic linkage. Since Man-P-Dol is believed to be formed only on the cytosolic face of the ER (Figure 2), and these modifications appear to occur on the luminal side of the ER, a Man-P-Dol flippase is essential for O- and C-mannosylation of proteins, as well as completing the synthesis of Glc₃Man₉GlcNAc₂-P-P-Dol and to maintain normal rates of protein N-glycosylation.

GPI Anchors

One class of proteins that is associated with membranes, despite not having any transmembrane domains, is attached by an amide linkage to GPI anchors. The biosynthesis of the GPI anchors theoretically requires at least two ER flippases. The best current evidence indicates that the early intermediate, GlcN-PI, is formed on the cytoplasmic face of the ER, and is subsequently translocated to the luminal monolayer where the GPI anchor is completed and the appropriate polypeptides are covalently attached to the ethanolamine moiety by a transpeptidation reaction. The completion of the anchor on the luminal

surface also requires Man-P-Dol as a mannosyl donor, and the transverse diffusion of the mannosyl intermediate requires a flippase that is discussed above (Figure 2).

Glucosylceramide

The enzyme that synthesizes glucosylceramide (Glc-Cer) from UDP-glucose and ceramide in an early Golgi compartment has an active site that is oriented toward the cytoplasm. As more complex cerebroside and gangliosides are elaborated on the interior of the Golgi compartments, it is necessary for the Glc-Cer formed on the cytosolic side to be translocated to the luminal leaflet where the glucosyl unit can be elongated by lumenally oriented glycosyltransferases. Thus, in this flippase-mediated event, the lipid moiety would be ceramide and the polar headgroup would be a β -linked glucosyl group, as illustrated in Figure 1(a). The biosynthesis of the complex glycosphingolipids also requires a set of Golgi proteins to mediate the transbilayer movement of the sugar nucleotides required for ganglioside synthesis. As there is experimental evidence that some fraction of the Glc-Cer formed on the cytoplasmic leaflet of an early Golgi compartment can be translocated directly to the inner surface of the PM, there may also be a PM flippase that mediates the movement of Glc-Cer to the outer leaflet.

Bacterial Cell Walls

In Gram-positive and Gram-negative bacteria, some of the building blocks for the assembly of peptidoglycan, lipopolysaccharide, and several other cell-wall complex glycoconjugates are synthesized on the inner face of the cytoplasmic membrane while attached to undecaprenyl pyrophosphate (Und-P-P). There is solid genetic evidence for the presence of membrane proteins that mediate the transbilayer movement of the bacterial lipid intermediates so the assembly of the cell-wall components can be completed on the exterior face of the cytoplasmic membrane, or in the case of Gram-negative bacteria, on the outer membrane. The Wzx family has been proposed to encode proteins involved in the translocation of Undec-P-P-linked intermediates in bacteria. There is recent evidence that the *wzx* gene encodes a protein involved in the transbilayer movement of a trisaccharide lipid intermediate in the biosynthesis of the enterobacterial common antigen in *Escherichia coli*. Although there is very limited information about their structures at this time, it is quite possible that the prokaryotic flippases resemble their eukaryotic counterparts. The intriguing question of why the polyisoprenoid glycosyl carrier lipids became longer (C55 for prokaryotes to C75–95

for eukaryotes) and acquired the saturated α -isoprene unit in dolichols during evolution remains to be explained.

Glossary

Adhesome The set of proteins and other molecules that are localized in adhesion sites (stably or transiently) and their direct interacting partners and regulators. The integrin adhesome is the subset of these components that is related to integrin-mediated cell–matrix adhesion sites.

Fibrillar adhesions Elongated or dot-like adhesions that are associated with fibronectin fibrils, mostly along the central areas of the cell.

Focal adhesions Flat elongated adhesions associated with prominent actin bundles (stress fibers); also known as ‘focal contacts’. They are usually located near the periphery of the cell.

Focal complexes Small dot-like adhesions located mainly at the edge of lamellipodium. They are induced by Rac, are associated with cell migration, and can develop into focal adhesions.

Podosomes Small cylindrical adhesions found in osteoclasts, macrophages, and various malignant cells.

Rac A Rho family guanosine triphosphatase (GTPase) that stimulates the extension of the lamellipodium and formation of focal complexes.

Rho A Rho family GTPase that stimulates stress-fiber and focal-adhesion formation.

Focal adhesions (also known as ‘focal contacts’) are integrin-dependent adhesions in which the cell membrane is attached at its external surface to the extracellular matrix (ECM), and at its internal aspect to the actin cytoskeleton. These transmembrane interactions are mediated via a complex network of cytoplasmic proteins, forming a submembrane plaque. Additional ECM–integrin–actin-mediated adhesion sites, termed ‘focal complexes’, fibrillar adhesions, three-dimensional (3D)-matrix adhesions, and podosomes, are related to focal adhesions, although the details of their molecular structures and functions differ. In addition to playing central roles in cell migration and morphogenesis, focal adhesions and related structures convey adhesion-triggered signals across the cell membrane, regulating cell proliferation, differentiation, and death.

Cell Adhesion

In multicellular organisms of the animal kingdom, cells adhere to their neighbors either directly, or via a complex meshwork of fibers known as the ECM. This adhesion is not a passive attachment but rather a complex process, mediating specific and dynamically regulated cell interactions as well as crucial signaling cross-talk between the cell and its environment. Indeed, cell adhesion plays a fundamental role in embryogenesis and organogenesis as well as in cellular processes such as cytoskeletal organization, cell motility, and regulation of the cell cycle and differentiation.

Moreover, cell adhesion is not a single, molecularly uniform, event but rather a highly diversified process at the cellular, molecular, and functional levels. For example, cell-to-cell adhesion occurs at tight junctions, gap junctions, chemical synapses, adherens junctions, desmosomes, and various carbohydrate-mediated contacts. Cell–ECM adhesions involve ECM proteins and glycosaminoglycans and their respective receptors, and occur at specialized cellular sites such as the

intermediate-filament-associated hemidesmosomes, and the widely occurring, actin-associated focal adhesion type, which is addressed here.

Focal Adhesions – A Structural Perspective

Specialized adhesions between cultured fibroblasts and the underlying substrate were revealed during the 1970s by interference–reflection microscopy and electron microscopy (Figure 1). These studies showed that the attached cells contain many specialized and defined regions (commonly measuring 0.25–2 by 2–10 μm) along the ventral plasma membrane, which are in very tight contact (10–15 nm gap) with the substrate. Moreover, these sites, which were termed ‘focal contacts’ or ‘focal adhesions’, appeared to be associated, within the cells, with the termini of actin microfilaments. These early studies revealed that focal adhesions are responsible for tight ECM contacts in which the extracellular substrate and the actin cytoskeleton are physically linked.

Following these early structural studies, the molecular composition of focal adhesions was addressed by immunofluorescence and immunoelectron microscopy, yielding a long list of diverse proteins, starting with α -actinin and vinculin. Biochemical examination of these proteins suggested that they are capable of establishing a complex network of protein–protein interactions with both cytoskeletal and signaling partners, and implicated focal adhesions in both mechanical and signaling processes. Studies carried out, in culture and *in vivo*, with different cell types exposed to a variety of conditions, established that focal adhesions are not the only form of ECM–integrin adhesions: included in this group are focal complexes, fibrillar adhesions, 3D-matrix adhesions, and podosomes (Figure 1).

Correlated fluorescence microscopy and cryo-electron tomography revealed the 3D features of focal adhesions,

Figure 1 Focal adhesions and related adhesion sites. (a) Stationary human fibroblasts, stained for actin (green) and vinculin (red), having typical oval focal adhesions located at the termini of actin stress fibers. (b) Migrating endothelial cells (porcine aortic endothelial cells, PAEC) stained for actin (green) and phosphotyrosine (red), displaying both focal adhesions (FA) and focal complexes (FX). Focal complexes have a dot-like morphology and are located at the edge of the lamellipodium, where actin is organized as a dense network of highly branched fibers. (c) Human fibroblasts stained for actin (green) and for the fibronectin receptor $\alpha_5\beta_1$ integrin (red), which is enriched in fibrillar adhesions. (d) A mouse osteoclast, stained for actin (green) and paxillin (red), showing typical podosomes – doughnut-shaped adhesions with an actin core. The insert shows a cluster of podosomes at a higher magnification. Scale = 10 μm .

Figure 2 Cryo-electron tomography (cryoET) of focal adhesions carried out by correlated fluorescence-cryoET. (a) REF52 cells expressing a fluorescent paxillin were cultured on EM grids, fixed, frozen, and areas identified by fluorescence as focal adhesions were examined using a cryo-electron microscope. The 3D rendered image provides a bottom view of a focal adhesion from which the ventral membrane (blue) was removed, in order to visualize the membrane-actin interface. The image shows an array of parallel actin filaments (tan), as well as doughnut-shaped particles (light green) located at the interface between the cytoskeletal filaments and the plasma membrane. (b) A scheme showing a lateral view of a focal adhesion, including the extracellular matrix (ECM), transmembrane integrins, the plasma membrane, the particles, short interconnecting filaments, and the parallel array of actin filaments (stress fibers). Based on Patla I, Volberg T, Elad N, et al. (2010) Dissecting the molecular architecture of integrin adhesion sites by cryo-electron tomography. *Nature Cell Biology* 12: 909–915.

showing that the actin stress fibers are attached to the plasma membrane via short filaments linked to membrane-attached, doughnut-shaped particles of around 25 nm in diameter (Figure 2). The molecular nature of these particles

is still unknown; however, they appear to interact directly with actin filaments and the plasma membrane, and thereby to anchor the actin cytoskeleton to the ECM-bound membrane.

The Molecular Organization of Focal Adhesions

More than 180 distinct proteins and other molecules – collectively termed the ‘integrin adhesome’ – were reported to be localized in, or directly associated with, focal adhesions and related adhesion sites (Figure 3). Constituent components are largely segregated into the three structural domains within these sites: the transmembrane domain, the cytoskeletal domain, and the interconnecting submembrane plaque (Figure 2).

The Receptors and Their ECM Ligands

The membrane domains of ECM adhesions contain specific integrins, which are heterodimers of α - and β -subunits that bind the ECM via a large extracellular domain. Integrins span the membrane and contain a cytoplasmic region through which they interact with plaque proteins. The most common integrins found in focal adhesions and related ECM adhesions are the fibronectin receptor, $\alpha_5\beta_1$, and the vitronectin receptor, $\alpha_v\beta_3$. Additional, somewhat less characterized membrane-bound components of focal adhesions include potentially adhesive molecules such as syndecan-4 (SDC4, Figure 3) and the hyaluronan-binding protein layilin (LAYN), as well as the tyrosine phosphatase LAR (PTPRF) and the glycoprotein SHPS1 (SIRPA), a substrate of the tyrosine phosphatase SHP-2 (PTPN11).

The Cytoskeletal Domain

Focal adhesions are associated with the termini of actin bundles termed ‘stress fibers’. The polarity of the attached actin filaments

is apparently uniform, with their barbed ends pointing to the membrane. That area of the actin network is particularly enriched with actin-associated proteins such as the actin-bundling protein α -actinin (ACTN1, Figure 3). Actin is also associated with the other forms of integrin-mediated adhesions, although not in the form of stress fibers (Figure 1). In addition to the actin system, cell–matrix adhesion sites can also be associated with, and regulated by, the microtubule cytoskeleton (TUBA1B) and intermediate filaments (vimentin; VIM).

The Submembrane Plaque

The submembrane plaque is a multiprotein complex that interconnects actin to the membrane in focal adhesions and related adhesions (Figure 3). Some of the plaque components contain binding domains for both actin and integrins, including talin, α -actinin, tensin (TNS1, Figure 3), and filamin (FLNA), and may function as direct integrin–actin linkers. Additional integrin-associated molecules do not bind directly to actin, and may link the cytoskeleton to the membrane indirectly, via other plaque components. Some of them, such as focal adhesion kinase (FAK; PTK2), the LIM-domain protein DRAL (FHL2), and integrin-linked kinase (ILK), are signaling molecules (Figure 3).

Yet another group of focal adhesion-associated proteins includes actin-binding proteins that were not shown to interact directly with integrins, such as vinculin (VCL), VASP/Ena (EHAH), and ezrin–radixin–moesin (ERM) proteins (VIL2, RDX, MSN) (Figure 3). VCL plays a pivotal role as a central linker interacting with many plaque proteins – such as talin (TLN1), α -actinin, VASP/Ena, ponsin, and vinexin (SORBS3) – as well as with acidic phospholipids and actin. Finally, a very

Figure 3 The integrin adhesome network. This network is divided here into structural (center) and regulatory/signaling (left and right) sub-networks. The structural part consists of actin, integrins (ITGA, ITGB) and other adhesion receptors (light brown ellipses), cytoskeletal proteins (cyan ellipses), actin modulators (light green), and multidomain adaptor proteins (red). The regulatory/signaling part includes small GTPase proteins and their activators and inhibitors (blue hexagons, rectangles, and ellipses, respectively), tyrosine kinases and phosphatases (orange rectangles and ellipses), serine/threonine kinases and phosphatases (yellow rectangles and ellipses), phospholipids (and their hydrolysis products), phosphatidylinositol kinases, phosphatidylinositol phosphatases and phospholipases (pink hexagons, rectangles, ellipses, and diamonds), chaperones and mediators of protein degradation (black and gray), and regulators of transcription and translation (mint green rectangles). Integrin adhesome data are largely based on Zaidel-Bar R and Geiger B (2010) The switchable integrin adhesome. *Journal of Cell Science* 123: 1385–1388, and <http://www.adhesome.org>.

large group of proteins consists of adapter proteins that apparently interact with actin-bound and integrin-bound components and link them to one another.

The components of cell–matrix adhesions have an unusually wide range of intrinsic activities. Beyond their protein–protein binding specificities, many of these proteins are enzymes, such as tyrosine kinases, serine/threonine kinases, tyrosine phosphatases, inositol 5′-phosphatase, modulators, and adapters of small guanosine triphosphatases (GTPases), and other enzymes such as PI 3-kinase (PIK3CA) and protease calpains (CAPN1/2) (Figure 3). It should be pointed out that the true molecular complexity of focal adhesions is probably greater than that depicted in Figure 3 because many of these components represent products of multigene families, and may undergo posttranslational modification and proteolytic cleavage.

A striking characteristic of many focal-adhesion components is that they are multidomain proteins that can interact with several distinct partner molecules. For example, vinculin, FAK, Src family kinases, and paxillin (PXN) can each bind to more than 10 different partners. Thus, the theoretical number of different combinations of molecular interactions that might be involved in linking integrins to actin is enormous. Importantly, most interactions between focal-adhesion components are not constitutive, but can be tightly regulated by local intra- and extracellular cues. Therefore, the pool of adhesome

components within a cell can give rise to a variety of adhesion sites with diverse structures, molecular compositions, and functions.

Diversity of Cell–Matrix Adhesion Sites

Adhesions with the ECM are formed by essentially all adherent animal cells, in culture and *in vivo*. Yet their morphology, size, molecular composition, and subcellular distribution can be quite heterogeneous. These adhesions, however, share two common features: they are mediated by integrins, and they interact with the actin cytoskeleton. Focal adhesions, the best-characterized form of these sites, are flat elongated structures, several square microns in area, and are usually located near the periphery of cells, associated with bundles of actin microfilaments (Figures 1 and 3). The development of focal adhesions is stimulated by the small GTPase Rho, and requires actomyosin contractility. Characteristic focal-adhesion plaque proteins include vinculin, talin, paxillin, and tyrosine-phosphorylated proteins. Focal adhesions are particularly prominent in cultured cells growing on solid surfaces; yet structures with similar molecular properties are also found *in vivo*.

Another group of matrix adhesions is the focal complexes, which are small, dot-like adhesions mainly found close to the edges of the lamellipodium (Figures 1 and 4). These sites can

Figure 4 A simplified scheme highlighting major pathways of focal adhesion-mediated signaling. Rho family GTPases, including Rho, Rac, and Cdc42, are regulated by integrins, growth factors (GFs), receptor tyrosine kinases (RTKs), and G-protein-coupled receptors (GPCRs). Cdc42 induces the formation of filopodia (not shown) and activates Rac. Rac induces the formation of a meshed network of branched actin filaments, extension of lamellipodia, and formation of focal complexes (FX). Rho induces actomyosin contractility and organizes actin in contractile bundles called ‘stress fibers’. Rho activation drives the development of focal adhesions from focal complexes. Rho-induced contractility is also essential for the development of fibrillar adhesions, and their translocation toward the cell center. In adhesion sites, integrins locally activate the tyrosine kinases, FAK and Src, which then regulate the enzymatic activities and interactions of many other focal adhesion components. Integrins also affect gene expression, mainly through the activation of the Ras–ERK pathway, and thereby regulate differentiation, proliferation, and survival.

be associated with cell migration or serve as precursors of focal adhesions. Their formation is induced by the Rho family GTPase Rac. In the more central locations of many cell types, there are the fibrillar adhesions (also referred to as ECM contacts), elongated or dot-like structures associated with ECM fibrils (Figures 1 and 4). The typical components of fibrillar adhesions are extracellular fibronectin fibrils, the fibronectin receptor $\alpha_5\beta_1$ integrin, and the cytoplasmic protein tensin. Fibrillar adhesions emerge from focal adhesions in an actomyosin-dependent fashion. Another form of ECM adhesions is the podosomes, small (around 0.5 μm in diameter) cylindrical structures containing typical focal adhesion proteins such as vinculin and paxillin (Figure 1(d)). Podosomes are found in a variety of malignant cells and in some normal cells such as macrophages and osteoclasts. Characteristic and indispensable podosome proteins are gelsolin and dynamin, which localize to tubular invaginations of the plasma membrane typical for these structures. Finally, another type of adhesion is the 3D-matrix adhesion, formed with 3D ECM, which differ from focal adhesions in their overall morphology, fine molecular composition, and function.

Signaling

Focal adhesions and related structures are involved in adhesion-mediated signaling affecting various cellular processes such as proliferation, differentiation, anchorage-dependent survival, spreading, and migration. The main signaling paths include the stimulation of local tyrosine phosphorylation driven by FAK and Src, activation of small GTPases of the Rho and Ras families, and the extracellular signal-regulated kinase (ERK) pathway (Figure 4). It is proposed that tethering of FAK to clustered integrins leads to its autophosphorylation, recruitment of Src, and phosphorylation of their downstream targets. The presence of a variety of kinases and their substrates in the submembrane plaque suggests that additional signaling processes are activated by matrix adhesions; yet definitive information about these signaling processes is still scarce. Focal adhesions themselves are regulated by several signaling systems. In addition to Rho and Rac, excessive Src-mediated phosphorylation and stimulation of appropriate cells by growth factors (e.g., epidermal growth factor (EGF) or neuregulin), phosphatases, and proteases have a profound effect on the organization of cell–matrix adhesions.

Focal Adhesions and Mechanosensitivity

Mechanical forces play a key role in the development and fates of focal adhesions and focal complexes. The transition from focal complexes to focal adhesions and the growth of focal adhesions require local, actomyosin-generated tension, and are dramatically suppressed following treatment with inhibitors of Rho kinase or of myosin light-chain kinase (Figure 5). The mechanisms underlying adhesion-mediated mechanosensing are still poorly understood; yet it is likely that forces applied to the adhesomal network affect the conformation of some of the scaffolding or signaling constituents, thereby blocking or enhancing signaling events, thereby altering the

Figure 5 The key role of actomyosin contractility in the organization of adhesion sites. Rat embryonic fibroblasts (REF52), stably expressing β_3 -integrin-GFP, were either (a) untreated (control) or (b) treated with the Rho-kinase inhibitor Y-27632, prior to fixation. Inhibition of actomyosin contractility by Y-27632 causes disassembly of focal adhesions, and accumulation of focal complexes. Scale = 10 μm .

scaffold's organization. Recent data indicated, for example, that force stretches some of the plaque proteins (such as Crk-associated substrate (CAS) and talin) and thereby regulates their interactions. Focal complexes do not appear to be stimulated by actomyosin contractility, and even become abundant upon inhibition of contraction (Figure 5). Similarly, the maintenance of fibrillar adhesions is not affected by the inhibition of contractility; yet their emergence from peripheral focal adhesions requires actomyosin-driven tension.

Folate and Vitamin B₁₂ Function

B Shane, University of California, Berkeley, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Cobalamin Another name for vitamin B₁₂.

Coenzyme B₁₂ Also called 5'-deoxyadenosylcobalamin.

H₄PteGlu_n A polyglutamate form of tetrahydrofolate (tetrahydropteroylglutamate).

Megaloblastic anemia A large cell anemia.

Neural tube defects Birth defects such as spina bifida and anencephaly due to incomplete closure of the neural tube during development.

Pteroylmonoglutamate Another name for folic acid.

Folate Structure and Chemistry

Folate is a generic term for a family of chemically and functionally related compounds based on the folic acid (pteroylmonoglutamate) structure (Figure 1). Folic acid is an oxidized, synthetic form of the vitamin and is reduced within the cell to the metabolically active 5,6,7,8-tetrahydrofolate form. Folates in tissues act as donors and acceptors of one-carbon units in metabolic reactions known as 'one-carbon metabolism'. These one-carbon units can be at the oxidation level of methanol (5-methyl-tetrahydrofolate), formaldehyde (5,10-methylene-tetrahydrofolate), or formate (5- or 10-formyl-tetrahydrofolate or 5,10-methenyl-tetrahydrofolate).

Practically all tissue folates are polyglutamate forms in which the glutamate tail is extended via an unusual peptide bond via the γ -carboxyl of glutamate. Glutamate chain lengths can vary from about 4 to 10 in human tissues. Metabolism of folates to polyglutamate forms is required for their biological activity as the polyglutamate forms are much more effective substrates for folate-dependent enzymes than are the monoglutamate derivatives, which are the transport forms of the vitamin. Conversion of folates to polyglutamates of chain length greater than three or more is also required for effective retention of folate by tissues.

Absorption and Transport

Food folates usually occur in a reduced, polyglutamyl form. Before absorption, they are cleaved to their monoglutamyl forms by a brush border glutamylhydrolase (glutamate carboxypeptidase II). Folates are absorbed in the proximal small intestine via the proton-coupled folate transporter (PCFT), an apically expressed transmembrane, pH-sensitive carrier that transports both oxidized and reduced folates with similar efficacy under the slightly acidic conditions of the gut wall. Folate monoglutamate in plasma is transported into peripheral tissues via the reduced folate carrier (RFC). This transmembrane carrier is specific for reduced folates with affinities in the low micromolar range while the affinity for folic acid is about 100-fold lower. The liver carrier transports both folic acid and reduced folates and is thought to be PCFT. Folate monoglutamate transported into cells is metabolized to polyglutamate forms by the enzyme folylpolyglutamate synthetase, which

catalyzes the adenosine triphosphate (ATP)-dependent sequential addition of glutamate moieties. Mitochondrial and cytosolic isozymes of folylpolyglutamate synthetase are encoded by a single nuclear gene.

A second family of closely related folate transporters known as 'folate-binding proteins' or 'folate receptors' (α , β , and γ) are expressed in a more limited range of epithelial tissues. The affinities of reduced folate monoglutamates for these receptors vary by receptor but are very high, usually in the low nanomolar range. This transporter is responsible for reabsorption of folate in the kidney by a receptor-mediated endocytotic process and is believed to play a similar role in folate transport in other tissues.

Folate Biochemistry and Functions

Folate coenzymes are involved in three major interrelated metabolic cycles in the cytosol of cells. These cycles are required for the synthesis of thymidylate and purines, precursors for DNA and RNA synthesis, and for the synthesis of methionine from homocysteine and the interconversion of serine and glycine (Figure 2).

5,10-Methylene-tetrahydrofolate plays a central role in these cycles as it can be used directly for thymidylate synthesis or it can be reduced to 5-methyl-tetrahydrofolate in the methionine synthesis cycle or can be oxidized to 10-formyl-tetrahydrofolate to be used in purine synthesis. Although the enzymes involved in these synthetic cycles are normally located in the cytosol, during the S phase of the cell cycle the enzymes involved in thymidylate synthesis translocate to the nucleus. Mammalian cells also contain a large, separate mitochondrial folate pool, which is involved in serine and choline metabolism and in the provision of one-carbon precursors for cytosolic one-carbon metabolism.

Serine-Glycine Interconversion

Serine is the major provider of one-carbon units for folate-dependent one-carbon metabolism. It donates its β -carbon to tetrahydrofolate to generate glycine and 5,10-methylene-tetrahydrofolate in a reaction catalyzed by the reversible pyridoxal 5'-phosphate (PLP)-dependent enzyme serine hydroxymethyltransferase (SHMT). Mammalian tissues contain

two distinct isozymes of SHMT, one cytosolic and one mitochondrial, encoded by different genes. The mitochondrial isozyme may be responsible for the generation of the majority of one-carbon units required for cytosolic one-carbon metabolism. 5,10-Methylene-tetrahydrofolate generated via the mitochondrial SHMT reaction can be oxidized to 10-formyl-tetrahydrofolate and then hydrolyzed to formate. The formate produced exits the mitochondria and the one carbon is reincorporated into the cytosolic one-carbon pool as 10-formyl-tetrahydrofolate. 10-Formyl-tetrahydrofolate can be reduced to 5,10-methylene-tetrahydrofolate in the cytosol via the action of a reversible trifunctional C1 synthase enzyme.

Nucleotide Synthesis

Folate is required for the synthesis of thymidylate, a nucleotide required specifically for DNA synthesis and repair. Thymidylate

synthase catalyzes the transfer of the one-carbon group from 5,10-methylene-tetrahydrofolate to the 5'-position of deoxyuridine monophosphate (dUMP) and its reduction to a methyl group to generate deoxythymidine monophosphate (dTMP) (Figure 2). The folate molecule also provides the reducing component in this reaction and the tetrahydrofolate is oxidized to dihydrofolate. The dihydrofolate generated has to be reduced back to tetrahydrofolate before it can be reutilized in one-carbon metabolism in a reaction catalyzed by dihydrofolate reductase (DHFR). Thymidylate synthase (TS) activity is primarily expressed in replicating cells during the S phase of the cell cycle and is highest in fast-growing cells. Consequently, drugs targeted to DHFR, such as methotrexate, have proven to be effective chemotherapeutic agents as they are selective inhibitors of rapidly growing cell. Some of the cytosolic folate enzymes involved in provision of thymidylate are sumoylated and translocate to the nucleus during the S phase of the cell cycle (3). These include TS, DHFR, and cytosolic SHMT.

Cytosolic folate coenzymes are also used in two steps of *de novo* purine biosynthesis (Figure 2). The C-8 and C-2 positions of the purine ring are derived from 10-formyl-tetrahydrofolate in reactions catalyzed by glycineamide ribonucleotide (GAR) transformylase and 5-amino-4-imidazolecarboxamide ribonucleotide (AICAR) transformylase. The enzymes involved in *de novo* purine are multifunctional and form a complex in the cytosol called the 'purinosome'. This complex remains in the cytosol during the S phase of the cell cycle.

Figure 1 Folic acid (pteroylmonoglutamate, PteGlu).

Figure 2 Folate-dependent cytosolic one-carbon metabolism.

Methionine Synthesis

The methylation of homocysteine to produce methionine uses 5-methyl-tetrahydrofolate as the methyl donor in a reaction catalyzed by methionine synthase, one of only two vitamin B₁₂-dependent enzymes in mammals (Figure 2). 5-Methyl-tetrahydrofolate is generated from 5,10-methylene-tetrahydrofolate in a reaction catalyzed by the flavoprotein methylenetetrahydrofolate reductase (MTHFR). Methionine can be metabolized to S-adenosylmethionine, which acts as the methyl donor in many reactions, including the methylation of DNA, histones and other proteins, neurotransmitters and phospholipid synthesis, and the synthesis of creatine. These methylation reactions play important roles in development, gene expression, and genomic stability. S-Adenosylhomocysteine, the product of methylation reactions, is a potent inhibitor of many methyltransferases and is catabolized by hydrolysis to adenosine and homocysteine. In liver and kidney, homocysteine can be further metabolized to cysteine via the transsulfuration pathway utilizing the PLP-dependent enzymes cystathionine- β -synthase (CBS) and cystathioninase. In most other tissues, homocysteine is exported to the circulation or is reconverted back to methionine via the folate-dependent methionine synthase reaction.

Homocysteine can also be remethylated to methionine by cytosolic betaine homocysteine methyltransferase (BHMT), a folate-independent enzyme that is expressed in high levels in liver and in some species, including humans, in kidney. Betaine (trimethylglycine) is derived by mitochondrial oxidation of choline. Dimethylglycine, the product of the BHMT reaction, is oxidized in the mitochondria to sarcosine (methylglycine) and then to glycine by the folate-dependent

flavoproteins dimethylglycine dehydrogenase and sarcosine dehydrogenase. Each oxidation results in the formation of a molecule of 5,10-methylene-tetrahydrofolate from tetrahydrofolate.

Methionine is a dietary essential amino acid and it is often the most limiting amino acid in human diets. Methylation reactions account for a large proportion of the methyl group intake in humans and the methionine synthase and BHMT reactions allows salvage of its backbone after its use for methylation.

Chemistry of Vitamin B₁₂

Vitamin B₁₂ (cobalamin) consists of a central cobalt atom surrounded by a heme-like planar corrin ring structure (Figure 3), with the four pyrrole nitrogens coordinated to the cobalt. It contains a phosphoribo-5,6-dimethylbenzimidazolyl side group, with one of the nitrogens linked to the cobalt by coordination at the bottom position. The lower axial ligand is usually replaced by an active site histidine residue when bound to protein. The upper axial position can be occupied by a number of different ligands, including methyl, hydroxyl, and 5'-deoxyadenosyl groups, and by cyanide in what is commonly known as vitamin B₁₂ (cyanocobalamin). In cyanocobalamin and the naturally occurring hydroxy cobalamin forms, the cobalt atom is trivalent Co³⁺ (cob(III)alamin), the most oxidized form. The coenzyme forms of the vitamin are the unliganded, fully reduced Co¹⁺ derivative or cob(I)alamin; 5'-deoxyadenosylcob(III)alamin, also known as coenzyme B₁₂; and methylcob(III)alamin.

Figure 3 Structure of vitamin B₁₂ (cyanocobalamin).

Absorption and Transport of Vitamin B₁₂

Vitamin B₁₂ in food is bound to protein and is released in the stomach by the acid environment and by proteolysis of binders by pepsin. It then binds to other proteins known as R binders and these complexes have to be hydrolyzed by proteases in the small intestine before the B₁₂ is available for absorption. The parietal cells in the stomach secrete a 50-kDa glycoprotein called 'intrinsic factor (IF)' that can bind vitamin B₁₂ after its release from the R binders. Vitamin B₁₂ is absorbed via receptors located at the distal ileum at the end of the small intestine. In the presence of Ca²⁺, the IF-B₁₂ complex binds to the IF receptor (cubilin), and the complex is internalized by a receptor-mediated endocytotic process. The IF is degraded and vitamin B₁₂ is released into the cytosol and into the circulation, and binds to a 38-kDa protein called 'transcobalamin II (TC-II)'. Vitamin B₁₂ can also be absorbed by a diffusion-like process, but this is very inefficient (less than 1%). TC-II-B₁₂ is transported into tissues by receptor-mediated endocytosis, in this case via the TC-II receptor.

Vitamin B₁₂ Biochemistry and Functions

Mammals use vitamin B₁₂ as a cofactor for two enzymes, cytosolic methionine synthase (described above), which utilizes methylcob(III)alamin as the cofactor, and mitochondrial methylmalonyl CoA mutase, which uses 5'-deoxyadenosylcob(III)alamin as its cofactor. Vitamin B₁₂ is released into the cytosol of cells as hydroxycob(III)alamin and is reduced to cob(I)alamin. Cob(I)alamin is then methylated to methylcob(III)alamin after binding to methionine synthase. Alternatively, vitamin B₁₂ can be transported into the mitochondria and reduced, and the 5'-deoxyadenosyl ligand added from ATP in a reaction catalyzed by a deoxyadenosyltransferase. Rare human genetic defects in many of these steps in vitamin B₁₂ metabolism have been described.

Methionine Synthase

Methylcobalamin is a cofactor for the previously described folate-dependent methionine synthase involved in homocysteine remethylation (see [Figure 2](#)). Methionine synthases are large, monomeric Zn metalloproteins and consist of three domains: a catalytic domain containing the binding sites for 5-methyl-tetrahydrofolate and homocysteine, a B₁₂ domain in which the B₁₂-cofactor binds, and an accessory protein domain. The cob(I)alamin cofactor is methylated by 5-methyl-tetrahydrofolate, generating enzyme-bound methylcob(III)alamin and releasing tetrahydrofolate, and then methylcob(III)alamin transfers its methyl group to homocysteine to generate methionine and regenerate the enzyme-bound cob(I)alamin cofactor. The cofactor is occasionally oxidized to the nonfunctional cob(II)alamin form during catalysis. The enzyme is reactivated by methionine synthase reductase, an accessory protein that catalyzes the adenosylmethionine and NADPH-dependent reductive methylation of enzyme-bound cob(II)alamin to methylcob(III)alamin. The gene (*MTRR*) for a single human methionine synthase reductase protein that

contains binding sites for nicotinamide adenine dinucleotide phosphate reduced (NADPH), flavin adenine dinucleotide (FAD), and flavin mononucleotide (FMN) has been cloned. It belongs to the P450 reductase protein family. Human mutations that result in loss of methionine synthase activity and early onset megaloblastic anemia fall into two complementation groups. The *cblG* complementation group results from mutations in the structural gene for methionine synthase (*MTR*) whereas mutations in methionine synthase reductase (*MTRR*) are responsible for the *cblE* complementation group.

Methylmalonyl CoA Mutase

Mitochondrial β -oxidation of dietary odd-chain fatty acids produces propionyl CoA in addition to acetyl CoA. Propionyl CoA is converted to D-methylmalonyl CoA in a reaction catalyzed by the biotin-dependent propionyl CoA carboxylase. Propionyl CoA and methylmalonyl CoA can also arise during catabolism of isoleucine, valine, methionine, and threonine. A racemase converts D-methylmalonyl CoA to L-methylmalonyl CoA, and the 5'-deoxyadenosylcobalamin-dependent methylmalonyl CoA mutase catalyzes the conversion of L-methylmalonyl CoA to succinyl CoA. All these reactions occur in the mitochondria, and the succinyl CoA formed has several potential fates, including entry into the citric acid cycle and heme biosynthesis.

Folate Deficiency

Folate deficiency is usually due to a dietary insufficiency although it can arise from other causes such as malabsorption syndromes. The classical symptom of folate insufficiency is megaloblastic anemia, a condition reflecting deranged DNA synthesis in the erythropoietic cells. Blood cells are enlarged and often multinucleated. Megaloblastic cells contain close to twice the normal DNA content and the DNA is partially fragmented. Many cells are arrested in the G2 phase just prior to mitosis. The defect in DNA synthesis in folate deficiency has been ascribed to defective thymidylate synthesis under these conditions with a resulting increase in uracil misincorporation into DNA. Removal of uracil by the repair enzyme uracil DNA glycosylase, and a decreased repair of the gaps produced by this enzyme, would lead to an increase in double-stranded DNA breaks under these conditions.

Neural Tube Defects

In the early 1990s, double-blind, randomized trials confirmed that supplemental folic acid given prior to conception and during early pregnancy significantly reduced by over 70% the occurrence and recurrence of neural tube defects (NTDs), the most common birth defects in humans. It is thought that some women and/or their offspring have a higher requirement for folate due to genetic reasons. The current fortification of the food supply with folic acid in the US and over 50 other countries arose because those individuals at risk for having an NTD child cannot be identified at the moment. NTD rates have fallen dramatically after fortification with the largest decreases in populations with the highest pre-fortification rates.

Vitamin B₁₂ Deficiency

Vitamin B₁₂ deficiency is rarely caused by a dietary insufficiency and most commonly arises from a defect in vitamin B₁₂ absorption. The classical manifestations are pernicious anemia, which is a megaloblastic anemia identical to that observed with folate deficiency, and a severe and often irreversible neurological disease called subacute combined degeneration of the spinal cord, which is characterized by demyelination and peripheral neuropathy.

In B₁₂ deficiency, the B₁₂-dependent methionine synthase enzyme is inactive and cytosolic folate is trapped as 5-methyl-tetrahydrofolate at the expense of other folate coenzyme forms required for one-carbon metabolism such as thymidylate synthesis, leading to a functional folate deficiency in the cell. As the defective DNA synthesis in pernicious anemia is caused by an induced secondary folate deficiency, high levels of folate can cause a hematological response in patients with megaloblastic anemia due to B₁₂ deficiency, but folate is ineffective in preventing the severe neurological pathologies associated with B₁₂ deficiency.

Defects in vitamin B₁₂ absorption affect a significant proportion of elderly people. Classical pernicious anemia is caused by an inability to absorb vitamin B₁₂ as a result of lack of production of IF. The disease is age related and is usually due to destruction of the parietal cells in the stomach, which is caused by an autoimmune disease in which antibodies to the H⁺,K⁺-adenosine triphosphatase (ATPase) or to IF are produced. Because body vitamin B₁₂ stores are usually ample at the onset of the disease and the turnover of body stores is slow, it can take many years before deficiency symptoms become apparent.

Malabsorption of dietary vitamin B₁₂ also can arise from any condition of decreased acid production or pancreatic

insufficiency. The prevalence of atrophic gastritis in subjects 50 years and older has been estimated at 10–30%, and many elderly people suffer from *Helicobacter pylori* infection. These conditions result in an impairment of food vitamin B₁₂ absorption because of an impaired ability to release the vitamin from protein binders, while absorption of vitamin B₁₂ in the absence of food is unimpaired.

The mechanism behind the neurological symptoms of vitamin B₁₂ deficiency is not currently understood.

Free Oligosaccharides: Formation and Degradation (Free Oligosaccharides Related to N-Linked Glycans)

T Suzuki, RIKEN Advanced Science Institute, Wako, Japan

© 2013 Elsevier Inc. All rights reserved.

Glossary

Chaperones Molecules that, by associating with substrates, prevent them from aggregation and assist their folding or assembly to form macromolecular structures.

Complex-type glycans Vertebrate *N*-glycans can be classified into three types based on their structures: high mannose, hybrid, and complex-type. In complex-type glycans, both α 1,3- and α 1,6-linked core mannoses are modified by GlcNAc residues, in most cases followed by galactose and sialic acid residues. Most cell-surface- or secreted glycoproteins contain complex-type *N*-glycans.

N-linked glycan An oligosaccharide linked by asparagine in the protein/peptide, a common

modification in all eukaryotic proteins that go through the secretory pathway.

***N,N'*-diacetylchitobiose** A dimer of *N*-acetylglucosamine with β 1–4 linkage.

Proteasome A cytoplasmic gigantic protease complex involved in various cellular processes, including the degradation of misfolded proteins.

Quality-control machinery A system that maintains the quality of product, that is, newly synthesized proteins in the endoplasmic reticulum.

Sialic acid An acidic monosaccharide often found in nonreducing termini of vertebrate complex-type *N*- and *O*-glycans.

There is growing evidence that *N*-linked glycans play pivotal roles in protein folding and intra- or intercellular trafficking of *N*-glycosylated proteins. It has been known that during the *N*-glycosylation of proteins, significant amounts of free oligosaccharides (fOSs) are generated in the lumen of the endoplasmic reticulum (ER) by an unclarified mechanism. fOSs are also formed in the cytosol by enzymatic deglycosylation of misfolded glycoproteins destined to be degraded. Although the precise fate of intracellular fOSs remains obscure, recent studies have revealed that novel cellular machinery exists to process/degrade these glycans in a well-ordered, sophisticated fashion.

Free Oligosaccharides Formed in the Endoplasmic Reticulum

N-Glycosylation is one of the most common co- and posttranslational modifications of eukaryotic proteins occurring in the lumen of the endoplasmic reticulum (ER). During the translocation of proteins in the ER, an enzyme complex called oligosaccharyl transferase (OST) transfers an oligosaccharide (OS) moiety from the dolichol-linked donor substrate to asparagine residues located within the consensus sequence –Asn-Xaa-Ser/Thr– (where Xaa can be any amino acid except Pro) to form *N*-linked glycans on the nascent polypeptide chains. Although the biosynthesis of lipid-linked OSs, as well as processing of *N*-linked glycan chains on glycoproteins, is understood in detail, certain aspects of *N*-glycosylation reaction remain unknown. For instance, biochemical studies have shown that a significant pool of fOSs does occur in the lumen of the ER in mammalian cells. Although the exact molecular mechanism of the formation of these luminal fOSs still remains unknown, this release is clearly independent from the cytoplasmic peptide: *N*-glycanase (PNGase)-dependent process (see later; [Figure 1](#)).

These luminal glycans are believed to bear the *N,N'*-diacetylchitobiose structure at their reducing termini and are therefore called Gn2-type free glycans.

Free OS Transport System from the ER to the Cytosol

Although it is still not known whether fOSs have a physiological role in the ER, one would imagine that the accumulation of vast amounts of fOSs in the ER could interfere with the glycan-based quality-control system for nascent luminal proteins. Therefore, it is not surprising that cells have machinery to eliminate fOSs from the ER lumen. Using permeabilized cells and/or microsomes from mammalian sources, it has been demonstrated that fOSs in the ER can be exported into the cytosol in an adenosine triphosphate (ATP)-dependent manner. A gene encoding the transporter responsible for the export has not been identified. The OS export machinery appears to recognize the nonreducing mannose residues, but not the *N*-acetylglucosamine (GlcNAc) residue at the reducing terminus. The major structure of fOSs released from the ER to the cytosol has been shown to be $\text{Man}_{8-9}\text{GlcNAc}_2$ ([Figure 1](#)).

Free OSs Formed in the Cytosol: Its Connection with ER-Associated Degradation

Recent evidence clearly shows that the ER has quality-control machinery that differentiates between misfolded (glyco)proteins and correctly folded ones, so that only the latter exit from the ER to be delivered to their respective destinations. On the other hand, proteins that fail to fold or form functional subunit structures are retained in the ER and interact with various luminal chaperones that assist them to mature into their

Figure 1 Current proposed model for the fate of free oligosaccharides (fOSs) formed in and outside of the ER in mammalian cells. fOSs generated in the lumen of the ER by an undefined mechanism bear *N,N'*-diacetylchitobiose structures at their reducing termini (Gn2 glycans) (step (a)). After quick deglycosylation by α -glucosidases I/II (and sometimes ER α -mannosidase I) (step (b)), $\text{Man}_{8-9}\text{GlcNAc}_2$ is transported into the cytosol by an oligosaccharide transporter on the ER membrane (step (c)). fOSs can also be generated by the action of the cytoplasmic PNGase on misfolded glycoprotein, generating Gn2 glycans (step (d)). Putative pyrophosphatase, the activity of which is reported on the cytosolic side of the ER membrane, releases phosphorylated Gn2 glycans (fOS-P) from the dolichol-linked oligosaccharides (step (e)). The fOS-P can be converted into Gn2 fOS by the putative fOS-P phosphatase (step (f)). In the cytosol, ENGase acts on Gn2 glycans (and possibly fOS-P or misfolded glycoproteins) to form Gn1 glycans (step (g)). Gn1 glycans are now susceptible for the action of Man2C1, giving rise to specific $\text{Man}_5\text{GlcNAc}$ structures (step (h)). The isomeric structure of Man_5 is identical to that of the last biosynthetic intermediate on dolichol oriented to the cytosolic side of the ER. The $\text{Man}_5\text{GlcNAc}$ glycan (and possibly more trimmed $\text{Man}_{3-4}\text{GlcNAc}$ glycans) may be transported into the lysosomes by a specific oligosaccharide transporter, which remains to be identified (step (i)). The fOSs, incorporated into the lysosomes, are now hydrolyzed into monomeric sugars by lysosomal glycosidases for reutilization (step (j)). Note that this scheme cannot be applied to other organisms; for example, budding yeast *Saccharomyces cerevisiae* does not possess ENGase/Man2C1, and the occurrence of a totally distinct pathway for fOSs generation/degradation is reported.

functional structures. When proteins consistently fail to acquire the correct state, however, they eventually are degraded by the system called 'ER-associated degradation' or ERAD. It is now clear that this degradation process involves retrotranslocation of the defective proteins from the ER to the cytosol, followed by their degradation by the 26S proteasome. Evidence shows that glycan chains on glycoproteins play critical roles in monitoring the folding state of glycoproteins in the ER that involves various intracellular lectins.

When the misfolded glycoproteins are retrotranslocated to the cytosol for proteasomal degradation, the cytoplasmic PNGase can remove *N*-glycans from these glycoproteins before or during proteasomal degradation (Figure 1).

Another enzyme that can generate fOSs in the cytosol is a putative pyrophosphatase to generate phosphorylated fOSs (fOS-Ps) (Figure 1). Such enzyme activity has been detected mainly in mammalian cells. It has also been suggested that there may be fOS-P phosphatase activity to generate Gn2-type fOSs, but the molecular nature of these enzymes remains unknown.

Irrespective of their source, the cytosolic Gn2-type glycans can be converted into Gn1-type fOSs, bearing only a single GlcNAc residue at their reducing termini (Figure 1). This

reaction can be catalyzed by the action of endo- β -*N*-acetylglucosaminidase (ENGase). There is also a possibility that, in some cases, ENGase may release Gn1-type glycans directly from glycoproteins or dolichol-linked OS, while such reaction has not been unequivocally demonstrated. It should be noted, however, that a number of proteins with *N*-linked single GlcNAc, which is potentially formed by the action of ENGase, have been identified through proteomics approach. In mammalian cells, most of glycans accumulated in the cytosol are Gn1-type glycans, suggesting that ENGase action is not a rate-limiting step for fOS-catabolism.

Gn1 glycans formed in the cytosol can be further catabolized by the cytoplasmic α -mannosidase, Man2C1 (Figure 1). It has been shown that Man2C1 activity prefers Gn1 over Gn2 glycans as substrates, suggesting that reactions involving ENGase and Man2C1 are well ordered, that is, Man2C1 action follows ENGase. The final product of Man2C1 primarily is $\text{Man}_5\text{GlcNAc}$, which possesses the same isomeric structure as the biosynthetic intermediate of dolicholpyrophosphoryl OS (Figure 1). The $\text{Man}_5\text{GlcNAc}$ glycan is believed to be delivered into the lysosomes by a putative transporter for further degradation into monomeric sugars for reutilization. The nature of the lysosomal OS transporter is still unknown.

Species Specificity of Formation/Degradation of fOSs

Thus far, most of the studies on fOSs are based on ones using mammalian cells. However, there is accumulating evidence that the formation/processing mechanism of fOSs is distinct between different species. For instance, budding yeast (*Saccharomyces cerevisiae*) release fOSs almost exclusively by the PNGase-dependent pathway, while a PNGase-independent pathway appears to be dominant in mammalian cells. Also, in this yeast, all the detected fOSs were Gn2 type, and consistent with this observation, no ENGase activity was found in *S. cerevisiae*. In the worm *Caenorhabditis elegans*, neither enzyme activity nor orthologous gene for Man2C1 was found. Now, it is also clear that, while the gene for PNGase is well conserved among eukaryotes, the ortholog proteins in some species, such as *Neurospora crassa*, apparently have no enzyme activity as they retain critical mutations in the amino acid residues. Therefore, one could imagine that the formation/degradation process for fOSs should be determined in various distinct species to unveil the whole picture of this nonlysosomal glycan-processing pathway.

Formation of Complex-Type (Golgi-Type) Glycans

It should also be noted that processes depicted in [Figure 1](#) are only for high mannose-type glycans, and occurrence of fOSs with more processed glycans, that is, complex-type glycans in the case of mammalian cells, is just starting to be recognized. As a result, the molecular mechanism of their formation/degradation is completely unknown. In budding yeast, occurrence of PNGase-dependent, Golgi-modified fOSs are observed, suggesting that these fOSs should be derived from misfolded glycoproteins once they reach the Golgi apparatus. Because the Golgi-type (complex-type) glycans in mammalian cells contain not only mannose but also other sugars, such as sialic acid or galactose, the nonlysosomal catabolic pathway for complex-type glycans, if any, should be literally 'complex' than the case with the one for high mannose-type glycans that needs to be explored in the future.

Concluding Remarks

Cells possess a variety of enzymes/transporters to handle fOSs generated by several distinct mechanisms. Cytosolic fOSs, whether directly formed by the action of the cytoplasmic PNGase or transported into the cytosol from the ER lumen, are processed by ENGase and Man2C1 before being incorporated into the lysosomes for degradation. Why this rather complicated pathway is necessary for fOS catabolism is unknown. One notion is that this trafficking route enables them to be removed quickly from the ER, thereby preventing them from interfering with the efficient glycan-dependent quality-control system for newly synthesized glycoproteins in

the ER. However, it is still possible that a particular fOS itself may play a role in certain cellular processes. Indeed, fOS derivatives of *N*-glycan chains are suggested to play roles in the growth, senescence, and ripening of fruit in plants. Although similar bioactivity in other organisms still remains to be clarified, the identification of molecules involving formation, processing, and transport of fOSs should provide us more insight into the mechanism and function of this novel pathway.

Friedreich's Ataxia

P E Hart and A H V Schapira, University College London, London, UK

© 2013 Elsevier Inc. All rights reserved.

Glossary

Antioxidant Any substance that delays or prevents the progress of oxidation.

Ataxia Incoordination of voluntary muscle action.

Mitochondria Cytoplasmic organelle, consisting of an outer membrane and an inner folded membrane, and containing its own DNA.

Mitochondrial DNA A circular DNA molecule of 16.5 kb contained within the mitochondrion and inherited maternally.

Mitochondrial respiratory chain A series of enzyme complexes located on the mitochondrial inner membrane responsible for generating a proton gradient, which is itself required for the conversion of adenosine diphosphate to adenosine triphosphate (ATP) by complex V (ATP synthase) of this chain.

Trinucleotide repeat A three-nucleotide sequence, present in normal individuals as a set number of repeats, but which causes disease when a threshold number of repeats are exceeded.

Friedreich's ataxia (FRDA) is an autosomal recessive disorder that causes ataxia, sensory loss, cardiomyopathy, skeletal abnormalities, and, in a proportion of patients, diabetes and optic atrophy. It is the most common inherited ataxia with an estimated prevalence of 1:29 000. Carrier prevalence is between 1:60 and 1:90. The responsible gene and its gene product, frataxin, have both been identified. Ongoing investigations into the function of frataxin and the pathophysiology of FRDA are opening up new avenues for therapeutic intervention in this devastating neurodegenerative disorder.

Historical Perspective

In a series of five papers published between 1863 and 1877, Nicholas Friedreich reported nine members of three families who had an onset in puberty of ataxia, dysarthria, sensory loss, muscle weakness, scoliosis, foot deformity, and cardiac symptoms. Areflexia was only described in the final two reports, but was later adopted as one of the clinical diagnostic criteria. Over a century later, the elucidation of the molecular mechanism of FRDA, and the availability of genetic testing for diagnosis, allowed greater clarity regarding the phenotypic spectrum of this disorder.

Clinical Features

Disease onset ranges from 1.5 to 51 years in reported series. Loss of ambulation has been reported to occur at a mean of 15.5 ± 7.4 years after disease onset but ranges between 3 and 44 years. Death is most commonly as a consequence of cardiomyopathy and is at a mean age of 37.5 ± 14.4 years. Retrospective analysis of disease progression has reported a mean time to wheelchair confinement of 11 years. Atypical presentations include onset over the age of 25 years (late-onset Friedreich's ataxia – LOFA), the preservation of lower limb reflexes (Friedreich's ataxia with retained reflexes – FARR), and presentation as a pure spastic paraparesis, spastic ataxia (Acadian FRDA), pure sensory ataxia, or chorea.

Pathology

Pathological studies of FRDA report changes maximal in dorsal root ganglia, dorsal columns, corticospinal tracts, and heart. Macroscopically, the spinal cord is atrophic, with the posterior and lateral columns particularly affected. Changes within the nervous system are thought to be the consequence of a dying-back process from the periphery affecting the longest and largest myelinated fibers that show changes of an axonopathy. Demyelination is seen in the dorsal columns. The cerebellar cortex shows only mild neuronal loss, but the dentate nucleus and Clarke's column in the cord show marked changes. The cerebellar and occipital cortex show reduced phospholipid levels in the absence of neuronal loss.

Genetics

In 1988, the FRDA gene was mapped to chromosome 9. The gene was linked to 9q13-21.1 in 1990 and cloned in 1996. Ninety-eight percent of cases are now known to be the result of a homozygous GAA triplet repeat expansion in intron 1 of the FRDA gene. This is a unique trinucleotide repeat (TNR) disorder in that its inheritance is autosomal recessive, its location is intronic, and it involves a GAA trinucleotide as opposed to CAG repeat as found in the majority of TNR disorders. The repeat length in normal individuals is 6–34, but is expanded in patients and carriers to between 67 and 1700. Repeat lengths are unstable. Paternal transmission is associated with a reduction in repeat length, an effect that increases with increasing paternal age. Maternal transmission can cause an increase or decrease in repeat length, and expansions are greater with increasing maternal age. The remaining 2% of patients are compound heterozygotes harboring an expanded repeat on one allele and a point mutation on the other. Twenty-three different point mutations are described to date and include missense, frameshift, splice site, initiation codon, and non-sense mutations. The former are found only in the C-terminal, suggesting that functional domains reside in this part of the protein. The location of these mutations in highly or poorly

conserved amino acids correlates with the severity of the phenotype and the presence of atypical features. No cases resulting from homozygous point mutations have been described, although the population incidence of such individuals has been calculated to be $1:100 \times 10^6$. Clinically, typical FRDA may occur in individuals in the absence of linkage to chromosome 9, suggesting that a second locus may exist.

Phenotype–Genotype Correlations

Clinical parameters correlate with the repeat-length size. The size of GAA1 (the larger repeat allele) accounts for between 33% and 73% of the variation in the age of onset in various studies. GAA2 (the smaller allele) accounts for less than 20% of this variability. Indeed, GAA1 correlated better than GAA2 for several disease parameters and disease complications, including cardiomyopathy, in all studies except one. By contrast, the development of diabetes mellitus in FRDA correlated in only one study.

Further variation may result from other factors. The GAA repeat length may vary in a tissue-specific pattern due to mitotic instability, and peripheral blood samples may be a poor indicator of repeat lengths in pathologically affected tissues. GAA1 has been shown to differ in different brain regions and in various tissues. *cis*-Acting factors may also influence the phenotype. Potential mechanisms would include effects upon the stability of the trihelix structure by sequence alterations within or flanking the GAA expansion. Other genetic or environmental factors may also exert an influence on the phenotype. This is illustrated by the finding that the age of onset in sibs correlates strongly regardless of the degree of difference between their repeat lengths.

Gene and Gene Product

The FRDA gene contains seven exons within 80 kb of nuclear DNA. Transcription most commonly generates a 1.3-kb product translated into a 210-amino-acid protein named 'frataxin'. Alternative splicing generates a 171-amino-acid protein of uncertain significance. Frataxin and messenger RNA (mRNA) levels are maximal in tissues of high mitochondrial content (heart, pancreas, liver, and skeletal muscle), although not all of these exhibit obvious clinical involvement in FRDA. Within the central nervous system, mRNA levels are highest in the cord, low in the cerebellum, and very low in the cerebral cortex. Frataxin appears to play a role in development; its homozygous knockout is lethal at an early embryological stage. Frataxin mRNA levels are high in fetal spinal cord, dorsal root ganglion, heart, liver, skeletal muscle, and skin. Lymphocytes from patients with homozygous expansions contain low levels of frataxin, and this level and that of the mRNA are inversely related to the size of the smaller repeat. The block is thought to occur at the level of transcript elongation, and the mechanism for this is believed to be through the formation of unusual DNA structures, such as DNA triplexes, and sticky DNA by the GAA/TTC repeats. Several point mutations appear to alter the secondary structure of the protein, thus influencing mitochondrial uptake or cleavage.

The function of frataxin is incompletely understood. The amino acid sequence shows no strong homology to any proteins of known function. It has, however, been shown to contain an N-terminal mitochondrial targeting sequence in its first 55 amino acids. The predicted mitochondrial location was confirmed when tagged expressed frataxin was shown to co-localize with mitochondrial markers in HeLa and COS cells. An inner membrane and a matrix location within the mitochondrion have both been proposed. X-Ray crystallography studies reveal similarities to ferritin, a site for protein–protein interaction, and the ability to bind one molecule of iron. Point mutations in the protein core cause more severe phenotypes than those within the ferritin-like anionic patch or flat external protein interaction surface. Studies have confirmed that frataxin is critical for the formation of iron–sulfur (Fe–S) clusters and in their protection against oxidation, and in heme biosynthesis.

A number of animal and cell models of FRDA, including transgenic mice, have provided insights into the pathogenesis of FRDA. Increased susceptibility to oxidative stress, increase in cellular and mitochondrial iron content, defects of the Fe–S center-containing complexes of the mitochondrial respiratory chain, and reduced mitochondrial DNA levels have all been reported. Some of these changes have also been reported in human tissue. A role for frataxin in mitochondrial Fe–S center synthesis has been proposed. The exact relationship between these biochemical perturbations remains incompletely understood.

Therapeutic Intervention

Based on the improved understanding of the pathogenesis of FRDA, a number of novel therapeutic strategies have been evaluated. Iron chelation restores mitochondrial iron levels and prevents mitochondrial respiratory chain dysfunction in yeast models, but their *in vivo* use has been problematic. Antioxidants, including idebenone, coenzyme Q₁₀, vitamin E, N-acetyl cysteine, and selenium, have also been used. In some studies, idebenone has resulted in a decrease in cardiac hypertrophy and decreases in surrogate markers of oxidative damage to DNA. Other studies have failed to show a benefit. Combined therapy with coenzyme Q₁₀ and vitamin E has shown improvement in magnetic resonance spectroscopy and echocardiographic parameters and possibly slowing of neurological progression in a proportion of patients – particularly those with low coenzyme Q₁₀ levels at baseline.

Future therapeutic trials in FRDA may make use of antioxidants or other agents coupled to the triphenylphosphonium cation, which facilitates mitochondrial targeting of the agent. Potentials for gene therapy are also being explored, and may utilize drugs that interfere with the sticky DNA structures that are thought to be the cause of the transcription blockade that occurs in FRDA.

Glossary

Cofactor Organic or inorganic molecule bound (covalently or through noncovalent interactions) to the protein that is necessary for/aiding its function. For example, chlorophylls, quinones, and iron–sulfur clusters are cofactors in photosystem I.

F_A and F_B Low-potential [4Fe–4S] clusters that act as the terminal electron acceptors in type I photosynthetic reaction centers.

F_X A low-potential, interpolypeptide [4Fe–4S] cluster that acts as an intermediate electron

acceptor in type I photosynthetic reaction centers.

High-potential iron–sulfur proteins (HiPIP) These contain [4Fe–4S] clusters that operate between oxidation states of 3⁺/2⁺.

Low-potential iron–sulfur proteins These contain [4Fe–4S] clusters that operate between oxidation states of 2⁺/1⁺.

Type I Photosynthetic reaction centers that use [4Fe–4S] clusters as the terminal electron acceptors.

Type II Photosynthetic reaction centers that use a mobile quinone as the terminal electron acceptor.

Photosynthesis and Types of Photosynthetic Reaction Centers

Photosynthesis is the process by which solar energy is converted into chemical bond energy by plants and photosynthetic bacteria. Two types of photosynthetic reaction centers have evolved that are capable of performing light-induced charge separation. Type I reaction centers utilize iron–sulfur clusters as terminal electron acceptors, and type II reaction centers utilize a mobile quinone as the terminal electron acceptor. Type I reaction centers are present in green-sulfur bacteria, heliobacteria, and the recently discovered phototrophic acidobacteria, and as photosystem I (PS I) in cyanobacteria, algae, and higher plants. Type II reaction centers are present in purple bacteria and green-nonsulfur bacteria, and as photosystem II (PS II) in cyanobacteria, algae, and higher plants.

Oxygenic photosynthesis can be conveniently divided into two parts, the light reactions and the dark reactions. The light reactions employ four major membrane-bound multisubunit complexes in the energy-conversion process: PS I, PS II, the cytochrome *b₆f*-Rieske iron–sulfur complex, and adenosine triphosphate (ATP) synthase. In cyanobacteria and plants, the two reaction centers operate in series, producing oxygen as a by-product of the water-splitting reaction in PS II, and nicotinamide adenine dinucleotide phosphate, reduced form (NADPH) as a product of the reduction of nicotinamide adenine dinucleotide phosphate (NADP⁺) in PS I. A proton gradient is generated, in part, by the cytochrome *b₆f*-Rieske iron–sulfur complex and utilized by ATP synthase for the generation of ATP. During the dark reactions, carbon dioxide is enzymatically converted into carbohydrates at the expense of ATP and NADPH via the Calvin–Benson cycle. The chemical bond energy of ATP and NADPH is also used for cellular processes such as metabolism, growth, and reproduction.

Green-sulfur bacteria and heliobacteria contain only a type I reaction center and hence do not evolve oxygen. These bacteria are termed ‘anoxygenic phototrophs’ and thrive only

under low concentrations of molecular oxygen. The recently discovered *Candidatus Chloracidobacterium thermophilum* similarly contains only a type I reaction center but lives in an oxygen-containing environment.

Iron–Sulfur Clusters in Biology

Iron–sulfur clusters are among the most versatile cofactors in biology. They are involved in a wide variety of roles, such as imparting structural stability (endonuclease III and archaeal RNA polymerase), performing catalysis (radical S-adenosylmethionine (SAM) enzymes and aconitase), and carrying out the regulation of gene expression (SoxR). The most common function of iron–sulfur clusters, however, is in mediating biological electron transfer. Proteins that contain iron–sulfur clusters can be as simple as a bacterial dicluster ferredoxin or as sophisticated as the mitochondrial complex I.

There are four basic classes of iron–sulfur clusters. Each differs in the number of iron and sulfur atoms (**Figure 1**), resulting in a wide variety of cluster geometries, reduction potentials, and biological functions. (1) A single iron atom tetrahedrally coordinated by four cysteine ligands is present in rubredoxin. (2) A [2Fe–2S] cluster containing two iron atoms bridged by two sulfur atoms in a rhombic structure is present in plant ferredoxins. The iron atoms in a [2Fe–2S] cluster are typically ligated by cysteine residues, although Rieske iron–sulfur proteins employ two histidine ligands to one of the irons. (3) A [4Fe–4S] cluster containing four iron atoms and four sulfur atoms in alternate corner positions of a cube is present in bacterial ferredoxins. Each iron atom is ligated by a cysteine residue, although in rare instances one position is occupied by water or aspartate. (4) A [3Fe–4S] cluster with a geometry similar to that of a [4Fe–4S] cluster, except that one of the iron atoms is missing from the corner of the cube (**Figure 1**), is present in aconitase.

Figure 1 Schematic representation of the different types of simple iron–sulfur clusters found in biology. (a) Rubredoxin-like Fe center, (b) [2Fe–2S] cluster, (c) [3Fe–4S] cluster, and (d) [4Fe–4S] cluster.

Among these classes of iron–sulfur clusters, the [4Fe–4S] clusters are the most versatile because they can exist in three different oxidation states: 3^+ , 2^+ , and 1^+ . However, in any given protein, only one of the two oxidation–reduction pairs is used. High-potential iron–sulfur proteins (HiPIPs) employ the $3^+/2^+$ redox couple and exhibit midpoint potentials ranging from +50 mV to +450 mV. Low-potential iron–sulfur proteins employ the $2^+/1^+$ couple and exhibit midpoint potentials ranging from –200 mV to –700 mV. The protein environment plays a crucial role in determining which oxidation–reduction pair is used and in modulating the midpoint potential of the oxidation–reduction pair. Factors such as the immediate electrostatic environment, the number and strengths of H-bonds, solvent accessibility, and polarizability of the protein play important roles in modulating the thermodynamic properties of a given cluster.

Type I reaction centers contain three low-potential [4Fe–4S] $^{2+/1+}$ clusters termed F_X , F_A , and F_B . In the oxidized state, each [4Fe–4S] $^{2+}$ cluster contains two Fe^{2+} and two Fe^{3+} ions, which are manifest as two $Fe^{2.5+}$ – $Fe^{2.5+}$ mixed-valence pairs due to valence delocalization. As a result of paramagnetic coupling between the two $Fe^{2.5+}$ – $Fe^{2.5+}$ mixed-valence pairs, the net spin is zero and hence [4Fe–4S] $^{2+}$ clusters are diamagnetic. In the reduced state, a low-potential [4Fe–4S] $^{1+}$ cluster contains three Fe^{2+} ions and one Fe^{3+} ion, which are manifest as an equal-valence Fe^{2+} – Fe^{2+} pair and a mixed-valence $Fe^{2.5+}$ – $Fe^{2.5+}$ pair. The position of both pairs, with respect to protein ligands, can change at room temperature, and as a result, the mixed- and equal-valence pairs are free to migrate around the cube. However, because [4Fe–4S] $^{2+,1+}$ clusters are slightly distorted due, in part, to the interactions with an inhomogeneous matrix, preferential positions for both pairs exist. As a result of paramagnetic coupling between the equal-valence Fe^{2+} – Fe^{2+} pair and the mixed-valence $Fe^{2.5+}$ – $Fe^{2.5+}$ pair, the net spin is 1/2 and hence the [4Fe–4S] $^{1+}$ clusters are paramagnetic. The latter allows detection by low-temperature

electron paramagnetic resonance (EPR) spectroscopy. The EPR properties of a paramagnetic iron–sulfur cluster are additionally sensitive to the immediate protein environment, hence, a change in structure typically leads to a change in spectrum. EPR spectroscopy is especially advantageous for the study of cofactors in large protein complexes, wherein it is difficult to apply simpler techniques due to the presence of interfering chromophores or to the size of the biomolecule.

Type I Reaction Centers

Photosystem I

From a structural point of view, PS I is the best characterized of the type I reaction centers. A model based on the 2.5 Å resolution X-ray crystal structure of cyanobacterial PS I is available, providing detailed structural information on the three-dimensional (3D) arrangement of pigments, proteins, and cofactors (Figure 2). Each monomer of the cyanobacterial PS I complex contains 12 protein subunits, 96 chlorophyll *a* (Chl *a*) molecules, 22 carotenoids, four lipids, two phytylquinones, and three [4Fe–4S] clusters. PsaA (83 kDa) and PsaB (83 kDa) form the membrane-embedded heterodimeric core and contain the majority of the antenna molecules and redox cofactors. PsaC (9 kDa) is a membrane-extrinsic (stromal) subunit that contains the two terminal electron acceptors, F_A and F_B . PsaD (15 kDa) and PsaE (8 kDa) are stromal subunits and, along with PsaC, provide a docking site for the soluble electron acceptors ferredoxin and flavodoxin. Cyanobacterial PS I incorporates seven additional subunits (PsaF, PsaI, PsaJ, PsaK, PsaL, PsaM, and PsaX), many of which serve as chlorophyll-binding proteins.

The electron transfer chain includes a special pair of Chl *a* molecules termed ' P_{700} ', named for its peak absorbance in the visible region. According to current understanding, when P_{700} becomes excited to the singlet state, its electron is transferred to

Figure 2 Side view of the arrangement of all proteins in one monomer of cyanobacterial PS I (PDB entry 1JB0), with the main subunits indicated.

Figure 3 The arrangement of redox cofactors in cyanobacterial PS I with center-to-center distances depicted in Å (PDB entry 1JB0).

A_0 , a Chl a monomer (Figure 3). An additional molecule of Chl a (A) is located between P_{700} and A_0 that may act as an electron transfer intermediate. The initial $P_{700}^+A_0^-$ charge-separated state is stabilized by rapid transfer of the electron to a bound phyloquinone, termed A_1 , and then to a series of $[4Fe-4S]$ clusters, termed F_X , F_A , and F_B . The latter functions as a molecular wire, shuttling the electron to the stromal surface and making it accessible to ferredoxin or flavodoxin. Because the terminal electron acceptors are iron–sulfur clusters, and

because the core is composed of PsaA and PsaB subunits, PS I is termed a ‘heterodimeric type I reaction center’.

The Heliobacterial and Green-Sulfur Bacterial Reaction Centers

Although heliobacteria and green-sulfur bacteria employ a similar contingent of electron transfer cofactors, the polypeptides that bind the cofactors are significantly different.

A (PshA)₂ homodimer and a (PscA)₂ homodimer form the membrane-embedded cores of the heliobacterial and green-sulfur bacterial reaction centers, respectively. PshB in heliobacteria and PscB in green-sulfur bacteria bind the terminal F_A and F_B clusters.

The primary donor is a special pair of bacteriochlorophyll molecules termed P_{798} in heliobacteria and P_{840} in green-sulfur bacteria. The primary electron acceptor is considered to be a chlorophyll *a* derivative in both species. Similar to PS I, two branches of electron transfer cofactors are thought to exist that converge at the F_X cluster, with subsequent linear electron transfer to F_A and F_B . The participation of a quinone in forward electron transfer is still under debate in both heliobacterial and green-sulfur bacterial reaction centers.

The absence of a high-resolution crystal structure for a homodimeric type I reaction center from either heliobacteria or green-sulfur bacteria precludes visualization of the 3D arrangement of the redox cofactors and the polypeptide subunits. Structural inferences from biochemical and spectroscopic data rely heavily on using PS I as a model type I reaction center.

The F_X Cluster in Type I Reaction Centers

The F_X Cluster in Photosystem I

F_X is a interpolypeptide, low-potential $[4Fe-4S]^{2+,1+}$ cluster bound at the interface of the PsaA and PsaB polypeptides in PS I. It is one of the most reducing $[4Fe-4S]$ clusters known in biology, with a measured midpoint potential of -705 mV.

F_X is ligated by two cysteine residues from PsaA and two cysteine residues from PsaB that are part of highly conserved loop regions connecting the transmembrane α -helices *h* and *i* in both proteins (Figure 4). In addition to coordinating F_X , the loop regions shield the $[4Fe-4S]$ cluster from molecular oxygen. A well-protected environment around F_X is critical for stability, particularly during the assembly of PS I. Otherwise, the bridging sulfides (S^{2-}) of an iron–sulfur cluster would

Figure 4 A view of the loop regions that connect transmembrane helices *h* and *i* on PsaA (A-*hi*) and PsaB (B-*hi*) (PDB entry 1JB0). The loops contain the Cys residues that coordinate the F_X cluster, protect it from oxidative denaturation, and provide the Asp residues that form symmetric ionic bonds with PsaC.

become oxidized to the elemental S^0 state, and a persulfide bridge would be formed between the cysteine residues, causing loss of iron and degradation of the cluster. The loop regions on PsaA and PsaB also contain the negatively charged Asp residues that provide a portion of the binding surface for the PsaC subunit. The binding interface between PsaC and the PsaA/PsaB heterodimer will be discussed later in this article.

F_X exists in an $S=1/2$ ground-spin state and exhibits characteristic low-temperature EPR resonances at *g*-values 2.06, 1.86, and 1.76. Prior to the determination of the X-ray crystal structure of cyanobacterial PS I, the identity of F_X as a $[4Fe-4S]$ cluster was established by EPR and Mössbauer spectroscopy.

The F_X Cluster in the Heliobacterial and Green-Sulfur Bacterial Reaction Centers

The F_X -binding motif (FPCXGPXXGGTC, where X is a noncysteine amino acid) occurs in the PscA protein of green-sulfur bacteria and the PshA protein of heliobacteria. Although X-ray crystal structures are not available, there is little doubt that these two cysteine residues coordinate F_X in the (PscA)₂ homodimer of green-sulfur bacteria and the (PshA)₂ homodimer of heliobacteria in a manner similar to that in the PsaA/PsaB heterodimer of PS I. The F_X -coordinating loops in the PscA and PshA proteins do not contain the negatively charged Asp residues that are involved in PsaC–PsaA/PsaB interactions in PS I. It therefore appears that homodimeric type I reaction centers adopt a different mode of interaction with the F_A and F_B -containing protein. Interestingly, the F_X cluster appears to be relatively insensitive to oxidative denaturation in heliobacteria and green-sulfur bacteria, implying that the cysteine-containing loop regions shield the iron–sulfur cluster in a manner similar to that in PS I.

The magnetic properties of F_X are somewhat different in homodimeric type I reaction centers. It has long been known that the F_X cluster in PS I exists in an $S=1/2$ ground-spin state, whereas it has recently been shown that the F_X cluster in the green-sulfur bacterial and in the heliobacterial reaction centers exists in either an $S=1/2$ or an $S=3/2$ ground-spin state (or in a mixture of the two). The $S=1/2$ spin state is detected by EPR as rhombic resonances around $g=2$, and the $S=3/2$ spin state is characterized by low-field turning points between $g=4$ and $g=5$. Although the factors that force the coupling of the ferrous and ferric ions in cubane $[4Fe-4S]$ clusters into a particular spin state are not completely understood, a highly symmetrical environment surrounding an interpolypeptide $[4Fe-4S]$ cluster appears to be a common feature in proteins that fail to form an exclusive $S=1/2$ ground-spin state.

The F_A and F_B Clusters in Type I Reaction Centers

The terminal F_A and F_B acceptors in all type I reaction centers are low-potential $[4Fe-4S]^{2+,1+}$ clusters located on an extrinsic polypeptide. In PS I, the F_A cluster accepts an electron from F_X , and the F_B cluster donates the electron to soluble proteins such as ferredoxin and flavodoxin. The midpoint potentials of F_A and F_B are -530 mV and -580 mV, making

the $F_A \rightarrow F_B$ electron transfer step thermodynamically unfavorable. Although the presence of an uphill electron transfer step seems counterintuitive, the inverted midpoint potentials may play a role in preventing the formation of harmful oxygen-free radicals. Because the electron resides on the buried F_A cluster most of the time, the possibility that the exposed F_B cluster will transfer an electron by a collisional event with oxygen is minimized. In green-sulfur bacteria, which can survive only under low concentrations of oxygen, the F_A cluster is considered to be more reducing than F_B . Although this arrangement favors $F_A \rightarrow F_B$ electron transfer, the absence of oxygen renders the formation of harmful radicals moot. The precise midpoint potentials of the F_A and F_B clusters in the heliobacterial reaction center are yet to be measured.

The F_A and F_B clusters can be reduced either by the addition of a strong chemical reductant such as sodium hydrosulfite or by illuminating reaction centers at low temperature. In PS I, freezing a sample in the dark with subsequent illumination at 15 K promotes one electron from P_{700} to either F_A or F_B in a given PS I reaction center. Under these conditions, the resulting EPR spectrum is a superimposition of the resonances from F_A^- , with g -values of 2.05, 1.95, and 1.85 and F_B^- , with g -values of 2.09, 1.93, and 1.88. Freezing PS I complexes during illumination promotes multiple electron transfers, leading to the reduction of both F_A and F_B in a given reaction center. Here, the magnetic coupling between the reduced clusters results in a so-called interaction spectrum, which shows resonances at apparent g values of 2.05, 1.94, 1.92, and 1.88.

In the green-sulfur bacterial reaction center, the one-electron transfer illumination protocol leads to the preferential accumulation of F_B^- , and the two-electron illumination protocol results in additional accumulation of F_A^- . Because the midpoint potentials of the F_A and F_B clusters are not known with certainty, it is not yet possible to assign the EPR resonances in heliobacteria.

The F_A - and F_B -containing Proteins in Type I Reaction Centers

The PshB Polypeptide in the Heliobacterial Reaction Center

The identity of the protein that binds the terminal iron–sulfur clusters in heliobacteria remained elusive until it was discovered that the F_A/F_B -containing polypeptide, named PshB, was dissociated from the heliobacterial reaction center at relatively low ionic strength. The PshB protein was subsequently cloned and expressed in *Escherichia coli*, and the iron–sulfur clusters were chemically inserted *in vitro*. The recombinant PshB holoprotein was found to be capable of binding to the heliobacterial reaction center core and of accepting electrons from the F_X cluster.

The amino acid sequence of PshB contains two [4Fe–4S] cluster-binding motifs, one of which is a traditional CxxCxxCxxxCP motif and the other is a novel CxxCxxCxxxCC motif (Figure 5). It is not known whether the presence of a Cys residue instead of a Pro adjacent to the fourth Cys has functional or structural significance.

The PscB Polypeptide in the Green-Sulfur Bacterial Reaction Center

The PscB polypeptide in the green-sulfur bacterial reaction center is significantly different from its homologs, PshB and PsaC. First, the 23-kDa polypeptide has a unique, positively charged N-terminal domain, which is highly enriched in Lys, Pro, and Ala residues. A role in protein binding has been proposed for this domain, although there is no experimental evidence to support this conjecture. Second, although the C-terminal domain of PscB is similar to that of bacterial dicluster ferredoxins, it contains a novel CxxCxxCxxxCP Fe/S cluster-binding motif that ligates the putative F_A cluster (Figure 5). is not found in any other known dicluster ferredoxins. EPR and Mössbauer spectroscopic studies reveal that unlike recombinant PshB and PsaC, the two $[4Fe-4S]$ clusters cannot be properly inserted into recombinant PscB *in vitro*. Thus, PscB represents one of the few instances in which iron–sulfur clusters fail to become properly inserted into an expressed apo-ferredoxin.

The PscB polypeptide in the green-sulfur bacterial reaction center can be dissociated from the membrane core under conditions of moderate ionic strength. Thus, a loosely bound F_A/F_B -containing protein appears to be a common feature of homodimeric type I reaction centers. This finding indicates that in spite of the differences in the mass and composition of PscB and PshB, their mode of binding to the homodimeric type I reaction is likely to share more similarities than previously thought.

The PsaC Polypeptide in Photosystem I

PsaC is the best characterized of the F_A/F_B -containing proteins in type I reaction centers. The amino acid sequence of this 9-kDa polypeptide is typical of bacterial dicluster ferredoxins in that it contains two traditional CxxCxxCxxxCP cluster-ligating motifs and an amino acid sequence that is highly conserved in cyanobacteria, algae, and higher plants (Figure 5). The most similar residues are located at the PsaC–PsaA/PsaB binding interface, whereas the variable residues are usually located on the stromal face. Although PsaC is tightly bound to the membrane-associated PsaA/PsaB heterodimer, it is highly soluble in its unbound state. The ability to express large amounts of unbound PsaC via recombinant technology has allowed the determination of its 3D solution structure by nuclear magnetic resonance (NMR) spectroscopy. As expected, the iron–sulfur core of unbound PsaC shows the highest similarity to low-molecular-weight dicluster bacterial ferredoxins. The position, distance, and relative orientation of the two $[4Fe-4S]$ clusters as well as the conformation of two-cluster consensus binding sites are similar in PsaC and bacterial ferredoxins. In PsaC, the F_A cluster is ligated by Cys48, Cys51, Cys54, and Cys21, and the F_B cluster is ligated by Cys11, Cys14, Cys17, and Cys58. A fixed distance between F_A and F_B

is insured by the presence of a rigid one-turn α -helix between the third and fourth cysteine residues in each of the CxxCxxCxxxCP iron–sulfur cluster-binding motifs.

The presence of a high-resolution X-ray crystal structure of cyanobacterial PS I has provided structural details on the bound state of PsaC. PsaC is one of the very few membrane-associated proteins to have its structure solved in its unbound and membrane-bound states. The crystal structure of PS I-bound PsaC shows significant structural differences in the N- and the C-terminal regions when compared to unbound PsaC (Figure 6). The iron–sulfur core part of the protein largely remains unaltered, which is expected, given that clusters impart a high degree of rigidity to the central protein structure. The N-terminus, by contrast, is positioned closer to the F_A cluster and forms an anti-parallel β -sheet with the pre C-terminus. This conformation is significantly different than that observed in unbound PsaC wherein the N-terminus pushes the pre C-terminus away from the iron–sulfur core part of the protein. The C-terminus of PS I-bound PsaC assumes an extended conformation, which is strikingly different from the coiled-up structure encountered in unbound PsaC. The C-terminus is located in the binding interface of the PsaD and PsaA subunits; consequently, the high degree of structural flexibility of the C-terminus in unbound PsaC is altered to a fixed and extended form in the bound state of the protein. The uncoiling of the C-terminus is considered to play a crucial role during the orientation of PsaC on the PS I membrane core.

The structural differences between unbound and PS I-bound PsaC also have an effect on the midpoint potentials of the F_A and F_B clusters. In the unbound form, both the clusters have equivalent midpoint potentials of ~ -500 mV. On binding to membrane core, the midpoint potentials of F_A and F_B in PS I, respectively, become -530 mV and -580 mV.

The Tight Binding of PsaC with the PsaA/PsaB Heterodimer in Photosystem I

PsaC binds directly above the F_X -binding site, with the F_A cluster proximal to F_X . The binding site consists of an intricate network of ionic bonds (Figure 7) including one Lys and two

Figure 6 Structural differences between unbound PsaC (left, PDB entry 1K0T) and PS I-bound PsaC (right, PDB entry 1JB0). The N- and C-termini are indicated.

Figure 7 The network of ionic (*top*) and hydrogen bonds (*bottom*) between PsaC and the PsaA/PsaB heterodimer in photosystem I (PDB entry 1JB0).

Arg residues on PsaC, and four Asp residues on PsaA/PsaB, two of which are part of the extrinsic loop that provides the Cys residues that coordinates the F_X cluster. The network of Asp-Arg/Lys ionic contacts is highly C_2 -symmetric; R52_{PsaC} forms five ionic bonds with D568_{PsaA}/D579_{PsaA}, and K51_{PsaC}/R65_{PsaC} form five ionic bonds with D555_{PsaB}/D566_{PsaB}. If PsaC were rotated (*in silico*) 180° about the C_2 axis of symmetry, R52_C would still form five ionic bonds, but with D555_B/D566_B, and K51_{PsaC}/R65_{PsaC} would still form five ionic bonds, but with D568_{PsaA}/D579_{PsaA}. The equal division of the 10 ionic contacts between PsaA and PsaB represents a highly symmetric and extremely tight binding surface for the PsaC protein.

PsaC also forms three H-bonds (Figure 7) in a region of the P₇₀₀- F_X core distant from the ionic contacts, which breaks the otherwise perfect C_2 symmetry. These bonds are formed between T73_{PsaC}/Y80_{PsaC} on the C-terminus of PsaC and Q678_{PsaB}/K702_{PsaB}/P703_{PsaB} on a surface-located segment of PsaB. Unlike the symmetric ionic contacts, a symmetry-related binding pocket for the C-terminus of PsaC does not exist on the comparable surface-located segment of PsaA. Thus, the three H-bonds between the C-terminus of PsaC and PsaB break the binding symmetry, locking the PsaC protein into the correct orientation on the PsaA/PsaB heterodimer.

PsaC can be dissociated from PS I with high concentrations of chaotropes such as 6.8 M urea. This is in contrast to the reaction centers in heliobacteria and in green-sulfur bacteria wherein the F_A / F_B -protein can be dissociated with the use of 0.1–0.2 M NaCl. When released from the PsaA/PsaB heterodimer, the F_A and F_B clusters in unbound PsaC degrade due to the presence of oxygen, resulting in the loss of tertiary structure of the protein. A recent study in cyanobacteria showed that the extensive network of ionic and hydrogen bonds between bound PsaC and the PsaA/PsaB heterodimer are present to protect the F_A and F_B clusters against degradation by oxygen in organisms that contain PS II.

The terminal F_A and F_B clusters in the reaction centers of heliobacteria and green-sulfur bacteria do not require a comparable level of protection because the bacteria live in anoxic environments. By contrast, the F_A and F_B clusters in PS I have to function in a cell that is supersaturated with photosynthetically generated oxygen, and hence protection against oxidative degradation is required. It has been proposed that the extensive contacts between PsaC and the PS I membrane core developed as an evolutionary response to the onset of oxygenic photosynthesis ca. 3.5 billion years ago when the ancestor to PsaC may have been a loosely bound protein similar to PshB in heliobacteria.

Glossary

Actin stress fiber Bundles of actin microfilaments, which are found on the ventral side of cells cultured on artificial surfaces. They contain myosin and α -actin as well as a variety of other structural and regulatory proteins that allow them to contract and to exert tension. The ends of stress fibers terminate at specific sites at the plasma membrane (focal adhesions), which are involved in cell adhesion. Activation of RhoA has been shown to induce actin stress fiber formation.

Angiogenesis Growth of new blood vessels by sprouting from existing ones.

Cadherins Calcium-dependent adhesion proteins, characterized by the presence of cadherin repeats, which are present in the extracellular part of the protein. Cadherins mediate Ca²⁺-dependent homophilic adhesion. They are

divided into two subfamilies, the classic cadherins and the protocadherins. Classic cadherins are subdivided into four subfamilies, the type I classic cadherins, the type II classic cadherins, the desmosomal cadherins, and the so-called 'other classic cadherins'.

Guanine nucleotide exchange factors (GEFs) Proteins that catalyze the release of nucleotide bound to small guanosine triphosphatases (GTPases) such as RhoA. In most cases, GEFs bind to the guanosine diphosphate (GDP)-bound GTPase, causing dissociation of the GDP. GTP, which is present at higher concentrations in the cell than GDP, then binds to the GTPase, and the GEF is released.

RhoA Small GTP-binding protein (small GTPase). Being one of the best-studied members of the Rho-family of small GTPases, it has been shown to play an important role in the regulation of the actin cytoskeleton.

General Properties and Modifications

The α -subunits of G₁₂ and G₁₃, G α_{12} , and G α_{13} share 67% sequence identity and have a length of 377–380 amino acids. Biochemical analysis of purified G α_{12} and G α_{13} has revealed a relatively low rate of guanosine triphosphate (GTP) hydrolysis, as well as a relatively slow guanine nucleotide exchange rate. Their expression levels in most cells appear to be lower than those of other G-protein α -subunits. Both, G α_{12} and G α_{13} , undergo palmitoylation, a reversible posttranslational modification, which occurs at cysteine residues close to their N-termini. Palmitoylation localizes G₁₂ and G₁₃ to the inner side of the plasma membrane and is required for proper signaling via G₁₂/G₁₃. *In vitro* experiments have shown that purified G α_{12} is a substrate for protein kinase C, whereas G α_{13} can be phosphorylated by protein kinase A. The physiological significance of these phosphorylations is unclear.

Receptor-Mediated Activation of G₁₂ and G₁₃

It has been difficult to provide direct evidence for the coupling of a defined receptor to G₁₂/G₁₃. However, for a variety of GPCRs coupling to G₁₂/G₁₃ could be demonstrated using

different methods including the immunoprecipitation of receptor-activated G proteins, as well as genetic approaches. These studies revealed that some lipid mediators such as lysophospholipids or thromboxane A₂, various peptides such as endothelin, angiotensin II, or substance P as well as the protease thrombin act on receptors, which are able to couple to G₁₂/G₁₃ (Table 1). G₁₂ and G₁₃ appear to be activated by GPCRs, which also couple to G_q/G₁₁ and, in some cases, to G_i/G_o. However, not all G_q/G₁₁-coupled receptors are also able to activate G₁₂/G₁₃.

Cellular Functions of G₁₂/G₁₃

Most information on the cellular functions regulated via G₁₂/G₁₃ came from indirect experiments employing constitutively active mutants of G α_{12} /G α_{13} that lack the intrinsic GTPase activity due to an exchange of a glutamine residue (Q231 and Q226 in human G α_{12} and G α_{13} , respectively) to a leucine residue. Several laboratories could show that transfection of these mutants into different cell types leads to cellular transformation. Interestingly, human G α_{12} was first cloned in a screen for transforming oncogenes from an Ewing sarcoma complementary DNA library. In subsequent studies, the

Summarized are findings from various laboratories, which are based on the immunoprecipitation of receptor activated G_α₁₂/G_α₁₃ using photoaffinity labeling or a GDP/[³⁵S]GTPγS exchange assay as well as on genetic evidence from G_α₁₂/G_α₁₃ deficient cells. Please note that this list is far from being complete.

expression of constitutively active mutants of G_α₁₂/G_α₁₃ was shown to induce a variety of signaling pathways leading to the activation of various downstream effectors including phospholipase A₂, Na⁺/H⁺ exchanger, or c-Jun N-terminal kinase.

Another important cellular function of G₁₂/G₁₃ is their ability to regulate the formation of actomyosin-based structures and to modulate their contractility by increasing the activity of the small GTPase RhoA. The RhoA-mediated formation of actin stress fibers in fibroblasts activated by various GPCR agonists is one of the best-described cellular paradigms for G₁₂/G₁₃-mediated Rho activation and subsequent rearrangement of the actin cytoskeleton. This phenomenon involves a Rho-induced bundling of actin filaments into stress fibers and the clustering of integrins and associated proteins into focal adhesion complexes. The ability of G_α₁₂/G_α₁₃ to induce actin stress fiber formation in fibroblasts was first described by the group of Gary Johnson. Regulation of actin-based structures via a G₁₂/G₁₃-mediated and Rho-dependent pathway has also been shown to occur in many other eukaryotic cells. For instance, in neuronal cells, activation of Rho through lysophosphatidic acid or thrombin receptors leads to the formation of contractile actomyosin filaments, eventually leading to the induction of neurite retraction, cell rounding, or axonal growth cone collapse. In vascular smooth muscle cells, the G₁₂/G₁₃-Rho-mediated pathway has been shown to contribute to the vasoconstrictor-induced actomyosin-based cell contraction, and the same pathway appears to be involved in the platelet shape change response.

Proteins Directly Interacting with G_α₁₂/G_α₁₃

The activation of Rho by exchange of guanosine diphosphate for GTP is catalyzed by guanine nucleotide exchange factors (GEFs), which, in turn, are regulated by various, mostly ill-defined mechanisms in the cell. First indications that a Rho-GEF protein is regulated by G₁₂/G₁₃ came from studies on early

gastrulation events in *Drosophila*. Genetic analysis indicated that DRhoGEF2, a *Drosophila* RhoGEF protein, functions downstream of the *Drosophila* G_α₁₂/G_α₁₃ ortholog, the *concertina* gene product. Subsequently, three mammalian RhoGEF proteins (p115RhoGEF, post synaptic density protein (PSD95), *Drosophila* disc large tumor suppressor (DlgA), and zonula occludens-1 protein (zo-1)-domain (PDZ)-RhoGEF, and leukemia-associated RhoGEF (LARG)) were described that are able to interact with activated G_α₁₂/G_α₁₃. This family of RhoGEF proteins is characterized by the presence of a 'regulator of G-protein signaling' (RGS)-domain, which mediates the interaction with the α-subunits of G₁₂/G₁₃. Although the RhoGEF activity of PDZ-RhoGEF and LARG appears to be activated by both, G_α₁₂ and G_α₁₃, p115 RhoGEF activity is stimulated only by G_α₁₃. In addition, the RGS domains of these RhoGEF proteins accelerate the intrinsic GTP hydrolysis activity of G_α₁₂/G_α₁₃ *in vitro* and, thus, function as 'GTPase-activating proteins' (GAPs). Although it is now well established that RhoGEF proteins, which contain an RGS-domain, interact with G_α₁₂/G_α₁₃, the precise mode of this interaction is still not completely clear. In addition, several groups have found evidence for an involvement of tyrosine kinases in the regulation of Rho via G₁₂/G₁₃. In any case, regulation of RhoGEF proteins by G_α₁₂/G_α₁₃ provided the missing link between G₁₂/G₁₃ and their ability to activate the small GTPase RhoA, which then mediates the effects of G₁₂/G₁₃ on the cytoskeleton and may also be involved in the transforming activity of these G proteins (Figure 1).

Active G_α₁₂ and G_α₁₃ interact with the cytoplasmic domain of some type I and type II class cadherins, such as E-cadherin, N-cadherin, or cadherin-14, causing the release of β-catenin from cadherins (Figure 1). This downregulates cadherin-mediated cell activation, and the release of β-catenin from cadherins may be a mechanism by which G_α₁₂/G_α₁₃ induces cellular transformation.

Various other proteins including Bruton's tyrosine kinase, the Ras GAP Gap1m, radixin, heat-shock protein 90, or protein phosphatase type 5 have been shown to interact with G_α₁₂ and/or G_α₁₃ (Figure 1). However, the biological significance of these interactions is not yet clear.

In Vivo Functions of G₁₂/G₁₃

The fact that G₁₂/G₁₃ appears to be the major mediators of the activation of RhoA via GPCRs suggests that they are involved in multiple biological processes including morphogenetic processes, regulation of cell shape, or regulation of cell movements. Data on *in vivo* functions of G₁₂/G₁₃ came initially from the analysis of phenotypical changes of null-mutants of these G-protein α-subunits in mice, flies, and worms. Experiments in *Drosophila* have provided genetic evidence for a physiological role of the G₁₂/G₁₃/RhoGEF-mediated pathway leading to Rho activation. By gene inactivation and epistasis experiments, it could be shown that a signaling pathway, consisting of the G₁₂/G₁₃ ortholog *concertina*, the *Drosophila* RhoGEF protein DRhoGEF2, as well as of Rho, is involved in the actin/myosin-mediated cellular shape change, which results in the ventral furrow formation of the *Drosophila* embryo. Interestingly, loss of DRhoGEF2 results in a more severe phenotype than observed in *concertina* mutant embryos, suggesting that the *concertina* gene product conveys only part of the upstream regulation of DRhoGEF2.

Figure 1 Major signaling pathways regulated by G₁₂/G₁₃. Most receptors coupling to G₁₂/G₁₃ also couple to G_q/G₁₁ and, in some cases, also to G_i-type G-proteins. AT₁, ET_A, S1P₂₋₅, LPA_{1,2}, TP, PAR_{1,4} are some of the receptor subtypes that have been shown to signal through G₁₂/G₁₃ family G-proteins. Abbreviations: PLC-β, β-isoform of phospholipase C; IP₃, inositol-1,4,5-trisphosphate; DAG, diacylglycerol; PKC, protein kinase C; MLC, myosin light chain; RhoGEF, Rho-specific guanine nucleotide exchange factor; GTP, guanosine triphosphate; β-cat, β-catenin; eNOS, endothelial nitric oxide synthase; PP, protein phosphatase; RGS, regulator of G-protein signaling; AKAP, A-kinase anchoring protein; Pyk, proline-rich tyrosine kinase; JLP, JNK-interacting leucine zipper protein; ASK, apoptosis signal-regulating kinase; GRK, G-protein-coupled receptor kinase; ZO, zonula occludens; BTK, Bruton's tyrosine kinase; RasGAP, Ras-specific GTPase-activating protein; SNAP, soluble NSF attachment protein; Hsp90, heat-shock protein 90.

Table 2 *In vivo* functions of mammalian G₁₂/G₁₃ as revealed by conditional mutagenesis in the indicated cell types

Cell type	Function of G ₁₂ /G ₁₃
Platelets	G ₁₃ mediates ligand-induced shape change, contributes to aggregation and degranulation, is required for primary hemostasis and arterial thrombosis
Vascular smooth muscle	G ₁₂ /G ₁₃ are critically involved in the development of salt-dependent hypertension; not required for maintenance of basal blood pressure
Endothelium	G ₁₃ function in endothelial cells is required for embryonic angiogenesis
Neurons	G ₁₂ /G ₁₃ regulates radial migration of cortical neurons
Neural crest	G ₁₂ /G ₁₃ regulates cardiac morphogenesis
B lymphocytes	Humoral responses are impaired in the absence of G ₁₂ /G ₁₃ either due to reduced numbers of splenic marginal zone B cells or due to inappropriate trafficking of MZB-cells during immune responses
T lymphocytes	Increased susceptibility toward T-cell-mediated diseases

Although mice lacking the Gα₁₂ gene (*gna12*) are phenotypically normal, deletion of the Gα₁₃ gene (*gna13*) results in embryonic lethality at embryonic day 9.5 due to a defect in angiogenesis. Chemokinetic effects of thrombin were completely abrogated in fibroblasts lacking Gα₁₃, indicating that

Gα₁₃ is required for full migratory responses of cells to certain stimuli. The defects observed in Gα₁₃-deficient embryos and cells occurred in the presence of Gα₁₂, and loss of Gα₁₂ did not result in any obvious defects. However, Gα₁₂-deficient mice, which carry only one intact Gα₁₃ allele, also die *in utero*, and

G α_{12} /G α_{13} double-deficient mice die even earlier than G α_{13} single-deficient animals. This genetic evidence indicates that G α_{13} and its closest relative, G α_{12} , fulfill at least partially nonoverlapping cellular and biological functions, which are required for proper mammalian development.

In recent years, mouse lines carrying conditional null alleles of the genes encoding G α_{12} and G α_{13} have been generated (Table 2).

The conditional inactivation of G α_{12} and G α_{13} in glial and neuronal cells results in the overmigration of cortical neurons in particular regions of the cerebral and cerebellar cortices. This eventually leads to neuronal ectopia of the cerebral cortex and malformations of the rostral part of the cerebellar cortex, suggesting a role of G₁₂/G₁₃ in the radial migration of cortical neurons. In platelets lacking G α_{13} , but not G α_{12} , severe defects in the responsiveness to various platelet activators were observed, resulting in increased bleeding times and a protection of animals from the formation of arterial thrombi in a carotid artery thrombosis model. Several lines of evidence indicate a role of G₁₂/G₁₃ in the regulation of vascular tone. Although smooth-muscle-specific G α_{12} /G α_{13} deficiency did not affect basal blood pressure, it protected mice from the development of salt-induced hypertension, indicating that the increase in vascular tone responsible for salt-dependent hypertension involves G α_{12} /G α_{13} -mediated signaling in vascular smooth muscle cells. G₁₂/G₁₃-mediated signaling has also been shown to play particular roles in various immune cells. B-lymphocyte-specific G α_{12} /G α_{13} deficiency results in altered trafficking of marginal zone B cells during immune responses with defects in cellular polarization and migration. Lack of G α_{12} /G α_{13} in T-lymphocytes leads to increased activity of leukocyte integrins and abnormal proliferative responses resulting eventually in an increased susceptibility toward T-cell-mediated diseases.

Although G α_{12} and G α_{13} have been shown to possess oncogenic potential (see above), the *in vivo* relevance of this finding is still unclear. Recent *in vivo* data indicate that blockade of G₁₂/G₁₃-mediated signaling in a murine breast cancer cell line

did not affect tumor growth but rather reduced the metastatic spreading in a xenograft model, strongly indicating a role of G₁₂/G₁₃-mediated signaling in tumor progression.

Glossary

Allosteric Literally, at another site; proteins have domains, or sites, that carry out their functions, termed 'active' sites, such as the binding site on a receptor for the neurotransmitter ligand. Other ligands bind at different, or allosteric, sites, to modulate the activity of the protein.

Ligand-gated ion-channel receptor Some receptors are coupled to effector systems in the cells, possibly a cascade of events, while other receptors are themselves ion channels, regulated by binding of the neurotransmitter ligand.

Neurosteroids Steroids that are found endogenously in the nervous system and have some functions there. Neuroactive steroids have some action in the nervous system but may originate there or have exogenous sources, elsewhere in the body, or be administered as drugs.

Receptor proteins Proteins that recognize the signal molecule, the neurotransmitter, bind it, and trigger a response are called receptors.

Transgenic mouse An animal that has been genetically engineered to express a foreign gene (a 'trans' gene) or a mutated version of its own gene (knockout or knockin).

γ -Aminobutyric acid (GABA) is the major inhibitory neurotransmitter, mediating synaptic and tonic inhibition at virtually all nerve cells in the central nervous system (CNS). This amino acid is synthesized in one step from L-glutamate by the enzyme glutamic acid decarboxylase (GAD). GAD is present only in GABAergic neurons, comprising up to 30% of those in the nervous system of all organisms, and is a marker for GABA synapses. Dysfunction of GABA, including GAD, is implicated in a variety of neuropsychiatric disorders, including epilepsy, anxiety, depression, and drug dependence.

Fast inhibitory synaptic transmission is mediated primarily by the GABA type A receptor (GABA_A receptor = GABAR), a ligand-gated chloride ion channel. Some slow inhibition is mediated by GABA at the GABA type B (GABA_B) receptor, a G-protein-coupled receptor. GABARs are members of a neurotransmitter receptor super-family that includes the nicotinic acetylcholine receptors, glycine receptors, and serotonin 5HT₃ receptors. The nicotinic acetylcholine receptors and the GABARs are families of heteropentameric isoforms, or receptor subtypes. These have different age-dependent and brain regional localization, circuit participation, and, thus, involvement in different functions and behaviors. Despite the lack of X-ray crystallographic data on the structure of GABAR, considerable information about functional domains within the protein is evolving. GABARs are the targets of important drugs, including general anesthetics and agents used to treat epileptic seizures, anxiety, and sleep disorders, such as the benzodiazepines (BZs), and also mediate some effects of alcohol at low doses. BZs are synthetic compounds with important clinical utility (neuroactive drugs). The BZ receptor, or site that mediates their pharmacological effects, is a portion of the GABAR protein itself; indeed, the binding site appears to be a modified version of the binding site for GABA (see below).

Molecular Structure

Heteropentamers

The members of the super-family share a pseudo-symmetric, pentameric membrane-spanning structure, with all subunits

contributing equally to the ion channel (**Figure 1**). Each member of the super-family is made from a family of homologous subunits of 45–67 kDa, with a conserved topology. Each of these subunits possesses a long extracellular N-terminus, which in some cases carries the neurotransmitter-binding site, four membrane-spanning domains, including the ion channel wall in M2, and a large variable sequence intracellular loop between M3 and M4. Although the structure of these complicated oligomeric receptor-channel membrane proteins has so far not been solved by crystallographic methods, some structural information has been obtained for other kinds of membrane receptors, ion channels, and, particularly, the extracellular domain of the nicotinic acetylcholine receptor, found to be exactly homologous to a snail acetylcholine-binding protein. Additional structural information on the acetylcholine receptor has been obtained using computer-assisted electron microscope imaging.

A Family of Isoforms

The heteropentameric GABAR protein is most often made from α , β , and γ subunits. The most common combination contains two copies of one α subunit, two copies of one β subunit, and one copy of γ 2, arranged as in **Figure 2**. The isoform most abundantly expressed in the CNS contains α 1 β 2 γ 2. Six α subunits define the major subtypes. Those containing α 2 or α 3 are less abundant, and α 4, α 5, and α 6-containing GABAR are even less abundant, with very restricted regional expression. Each α has a preferential but not obligatory β partner (β 1, β 2, β 3, or θ , similar to avian β 4), because some α 's can combine with different β subunits in different regions. Some GABAR isoforms appear to contain two different α subunits, but these are relatively nonabundant. Additional rare isoforms have subunits substituted for γ 2. For example, the α 4 and α 6 subunits can combine with γ 2 or with δ in cerebellar and dentate gyrus granule cells and thalamic relay cells. Rarely, γ 1, γ 3, or ϵ (related to avian γ 4) can substitute for γ 2 in pentamers containing certain $\alpha\beta$ combinations.

Figure 1 Schematic of GABA_A receptors. The protein is shown as a pseudo-symmetric membrane-spanning ion-channel protein made of five homologous subunits, each of which has four membrane-spanning regions as shown in the pull-out subunit. The view from outside the cell (plan view) shows the arrangement around the central core, the chloride ion channel. Also indicated are the subunit families that can be utilized in composing each receptor, and the ligand-binding sites present on the receptor.

Figure 2 A three-dimensional-view donut model of GABA_A receptor heteropentamer with central pore and ligand-binding sites at subunit interfaces. The five subunits (β – γ – α – β – α) and five subunit interfaces are shown, each subunit having an extracellular domain (&) and a transmembrane domain (#). GABA and benzodiazepine (BZ) sites are indicated at β – α and α – γ subunit interfaces, respectively. The etomidate sites (*) are located in the transmembrane domain at β – α subunit interfaces, the same subunit interface as the GABA-binding site in the extracellular domain, around 50 Å away.

Anatomical Localization and Functional Heterogeneity

Each GABA_A subunit shows a specific anatomic and cellular localization as determined by assay of messenger RNA (mRNA) and polypeptides, indicating tissue-specific gene expression. Subunit-subunit associations and heteropentamer localization have been revealed by co-localization, co-purification, or co-immunoprecipitation studies. Furthermore, there is specific localization to subcellular sites on the plasma membrane, such as synaptic versus nonsynaptic regions and cell bodies versus axons and dendrites, including positioning at postsynaptic locations apposed to specific cellular inputs. For example, the abundant isoform $\alpha 1\beta 2\gamma 2$ is found primarily on inhibitory interneurons, thus inhibiting inhibition and producing a net excitatory circuit. Alternatively, many isoforms containing $\beta 3$ are partnered with $\alpha 2$, $\alpha 3$, and $\alpha 5$ subunits and localized on cells that use neurotransmitters other than GABA. These include principal excitatory cells, in which case GABA_ARs inhibit a local circuit. The $\alpha 1$ subunit appears to occur at any and all subcellular locations within a given cell, while the $\alpha 2$ is limited to axo-axonal synapses in some cells. Thus, the nature of the α subunit, or perhaps specific partnering, may play a role in localization. In addition, heterogeneity has been demonstrated in the developmental profile of individual subunits in brain regions and cells.

The heterogeneity in subunit composition for the GABA_A isoforms provides an explanation for pharmacological subtypes based primarily on ligand affinities, and secondarily on other factors such as sensitivity to regulatory systems. GABA_ARs in certain brain regions, with certain subunit compositions, vary in their sensitivity to modulatory drugs such as general anesthetics, including barbiturates, and BZs, as well as the biologically endogenous modulators, the neurosteroids. The neurosteroids are hormone metabolites that have rapid and direct effects on neurons, such as modulation of GABA_ARs. Metabolites of the female sex hormone progesterone (allopregnanolone), corticosteroids (tetrahydrocorticosterone), and, possibly, androgens enhance GABA_A currents and appear to reach effective concentrations during certain physiological and pathological conditions. This field of research is just in its infancy.

Insights Gained from Transgenic Mice

Interestingly, the specific anatomical location and circuitry of GABA_A subtypes dictate the specificity of functions and involvement in specific behaviors. Thus, transgenic and gene-targeted mice have demonstrated a role for certain subunits in particular functions and abnormalities, as well as pharmacology. For example, a mouse knockout for the $\gamma 2$ subunit reveals a role for this subunit in proper synaptic localization and clustering of GABA_ARs, and a role in anxiety, stress, and fear conditioning. Knockout of the $\beta 3$ subunit produces a severe phenotype with epilepsy, motor incoordination, hyperactivity, and cognitive defects. These observations suggest that decreased levels of $\beta 3$ subunit expression may contribute to Angelman syndrome, a human genetic disease with similar phenotype. Knockout of the common $\alpha 1$ and $\beta 2$ subunits has surprisingly little phenotype, perhaps due to compensatory increases in other subunits. Knockout of the $\alpha 6$ subunit reveals its obligatory partnership with the δ subunit in the cerebellum, because no δ peptide is expressed in surface receptors. Knockout or

knockdown of the $\alpha 5$ subunit yields an animal with improved spatial memory acquisition, implicating $\alpha 5$ -containing GABAR in the CA1 region in mechanisms that are inhibitory for learning. Genetic knockins of point mutations for drug-binding sites have revealed subunit and subtype functions such as the differential importance of the $\alpha 1$ subunit and its sites of expression in sedative/hypnotic functions, the $\alpha 2$ subunit in anxiety, and the $\beta 3$ subunit more so than $\beta 2$ subunit in the action of the intravenous anesthetic etomidate. Aberrant plasticity of GABAR in which a subunit switch occurs, such as $\alpha 1$ to $\alpha 4$, appears to contribute to drug withdrawal and seizure susceptibility. A summary of current (incomplete) knowledge of subtype subunit composition, localization, and function can be found in a recent review.

Subcellular Localization, Associated Proteins, and Synaptic Plasticity

The localization of GABAR likewise involves events other than gene expression, which include intracellular trafficking, surface membrane insertion, synaptic clustering, removal of GABAR from synapses, and recycling or degradation. For example, the nature of the β subunit seems to determine partially the subcellular location of GABAR. Regulation of these activities allows some plasticity of subunit composition of adult brain.

Several associated proteins have been identified in GABAR cell biology. These include especially gephyrin, originally isolated as a glycine receptor-associated synaptic clustering protein, which also appears to co-localize at synapses with some isoforms of GABAR. Likewise, GABARAP, a microtubule-associated protein, is involved in intracellular membrane vesicle trafficking and targeting of GABAR. GABARAP binds to the intracellular loop of the γ subunits but not others. As the $\gamma 2$ subunit is needed to direct GABAR to synapses, this interaction, as well as those with other proteins, may contribute to the process. Some aspects of channel function, allosteric modulation, and cell biology are regulated by posttranslational mechanisms including protein phosphorylation. Many such topics are still controversial.

Functional Domains

Assembly

Rules determining which pentamers are produced are built into the sequences of the subunits, primarily in the extracellular N-terminal domains. These residues involved in subunit partnering, assembly, and stoichiometry have been identified by subunit sequence scanning, site-directed chimeras, and mutagenesis. They involve homologous positions in different subunits and are located at regions of subunit interfaces (Figure 2). Thus, approximately two dozen isoforms are significantly present in the nervous system, out of the literally thousands of possible permutations of heteropentamers.

Ligand-Binding Sites

Although the presence of a γ subunit (generally $\gamma 2$) in the pentamer is required for BZ sensitivity, the nature of the α

subunit determines the BZ site selectivity. The δ subunit is selectively associated with the $\alpha 6$ subunit in cerebellar granule cells and with the $\alpha 4$ subunit elsewhere. Although isoforms containing $\alpha 4/6$ and $\gamma 2$ can bind BZ inverse agonists, $\alpha 4/6$ – δ isoforms are totally insensitive to traditional BZ, and they are excluded from synapses. The δ -containing isoforms are involved in producing tonic inhibition involving spillover of synaptic transmitter or other long-lasting pools of extrasynaptic GABA. These tonic currents are, therefore, affected by the activity of GABA transporters in nerve endings, postsynaptic cell bodies, and surrounding glia. The extrasynaptic δ receptors appear to have higher affinity for GABA than synaptic receptors, slower desensitization, and they are the main target of endogenous neurosteroid modulation, and certain exogenous modulatory drugs.

Inspection of sequences for the BZ-sensitive and insensitive α subunits suggested amino acid residues that are critical for BZ binding. The contribution of these residues was subsequently verified by site-directed mutagenesis and functional analysis by recombinant expression in heterologous cells. Additional information on ligand-binding site residues was obtained by microsequencing of peptides covalently attached by radioactive photoaffinity-labeled BZ ligand. Figure 2 summarizes results from the two approaches, indicating the general position of the BZ-binding site, one per pentamer; this is localized at the interface of α and γ subunits.

Similar approaches have identified residues involved in the agonist (GABA)-binding sites (two per pentamer), which are localized at the interface between β and α subunits (Figure 2). In fact, the residues in the β subunit that participate in the GABA-binding pocket are part of the BZ-binding pocket in the α subunit. This suggests that the binding site for BZ, a synthetic drug, is an evolutionary development of an agonist site. In addition, it is clear that the same residues in homologous sequences of other members of the receptor super-family are involved in the neurotransmitter-binding pocket, involving five to six small loops in the extracellular domain.

Ion Channel/Sites for Action of Allosteric Blockers and Enhancers

As in other members of the super-family, the second transmembrane domain M2 has been shown to form the ion channel in GABAR. Residues in this domain affect ion selectivity, gating, conductance, kinetics, and desensitization of the channel. This area is also involved in the action of picrotoxin and cage convulsants that functionally block the channel, as well as certain allosteric modulators such as general anesthetics that enhance GABA or activate the channel. Residues have been identified within the mouth of the ion channel in M2, as well as on the backside of the M2 helix, which are required for general anesthetic modulation of GABAR, suggesting the possibility of an anesthetic binding pocket, although this area may be involved only in allosteric coupling. Other residues near the extracellular ends of M3 and M1 have been identified as an actual binding site for the intravenous general anesthetic etomidate (two per pentamer) at the β/α interface (Figure 2) using photoaffinity labeling with an etomidate analog.

Glossary

Allotsterism A change induced in the properties and function of a receptor by attachment of a ligand to a site other than that utilized by the endogenous substrate.

Heterodimer A complex consisting of two different proteins.

Ligand A drug, hormone, or neurotransmitter that attaches to a receptor.

Recognition site That portion of a receptor to which the neurotransmitter or hormone attaches.

GABA_B-Receptor Structure and Function

The γ -aminobutyric acid_B (GABA_B) receptor was first identified in 1981. Studies revealed that (*R,S*)- β -aminomethyl- β -(4-chlorophenyl)-propanoic acid (baclofen), a drug used to treat spasticity, and GABA inhibit depolarization-induced neurotransmitter release and compete for a specific binding site in brain tissue. As neither the functional response to baclofen nor its binding is inhibited by bicuculline, a competitive GABA_A-receptor antagonist, it was proposed that baclofen interacts with a different class of receptors, which were designated GABA_B sites. Subsequent work demonstrated further that GABA_A and GABA_B receptors are distinct entities. Thus, although baclofen, like GABA_A-receptor agonists, hyperpolarizes neurons, the baclofen-sensitive receptors are coupled to G proteins, unlike the ionotropic GABA_A site. Activation of the GABA_B receptor decreases Ca²⁺ and increases K⁺ membrane conductance, whereas the GABA_A receptor regulates chloride ion flux. Although baclofen inhibits forskolin-stimulated adenylyl cyclase activity in brain tissue, it enhances cyclic adenosine monophosphate (cAMP) production in brain slices if they are exposed simultaneously to agents, such as β -adrenoceptor agonists, that activate receptors coupled to G_s. Thus, depending on the conditions, GABA_B-receptor stimulation either enhances or inhibits cAMP accumulation, suggesting an effector system associated with both G_i and G_o proteins. Furthermore, GABA_B receptor stimulation induces nuclear accumulation of transcription factors suggesting genomic consequences to activation of this site.

Definitive proof that the GABA_B receptor is molecularly distinct from the GABA_A site came from expression-cloning experiments. These studies revealed that the GABA_B receptor is a heterodimer composed of two seven-transmembrane-spanning proteins (Figure 1). The first protein to be identified was designated GABA_{B(1)}, and the second GABA_{B(2)}. These subunits, which have 54% amino acid similarity and 35% sequence homology, are characterized by a large extracellular N-terminal domain. Heterodimerization, which is essential for receptor trafficking to the membrane as well as receptor function, occurs predominately through association of the intracellular α -helical portions of the C termini (Figure 1).

The orthosteric-binding site for GABA is located within a conserved Venus flytrap region of the GABA_{B(1)}, but not GABA_{B(2)}, subunit N-terminal domain, whereas the affiliated G proteins are coupled to the GABA_{B(2)} component (Figure 1). The GABA_B site is a Group 3 receptor, a category that includes vomeronasal organ, metabotropic glutamate (mGluR), and calcium-sensing receptors. Indeed, calcium is absolutely required for agonist binding to the GABA_B site. Although several splice variants have been identified for the GABA_{B(1)}-receptor subunit, not all are capable of forming functional receptors when coupled to GABA_{B(2)}. The most extensively studied GABA_B-receptor subunit combinations are GABA_{B(1a)}/GABA_{B(2)} and GABA_{B(1b)}/GABA_{B(2)}. A variety of studies, including those with GABA_B subunit deletion mutant mice, have demonstrated that heterodimerization of these two distinct gene products is absolutely essential for a functional receptor, with homodimers being biologically inert. There is crosstalk between GABA_B-receptor signaling and other G-protein-coupled sites, such as mGluRs.

GABA_B receptors are located pre- and postsynaptically throughout the central nervous system (CNS) and in some peripheral organs. Even though heterodimerization is obligatory for GABA_B-receptor function, the distribution of GABA_{B(1)} and GABA_{B(2)} expression differs among brain regions, as do drug- or physiologically induced changes in subunit expression. This suggests a differential regulation of these genes, pointing to the possibility that the protein products may serve functions other than formation of GABA_B receptors. For example, it has been reported that GABA_B-receptor subunits can directly associate with other proteins, including transcription factors.

The restricted number of GABA_B-receptor subunits, the 1:1 stoichiometry of the system, and the conserved nature of the GABA_{B(1)}-neurotransmitter recognition site, limits the possibilities for pharmacologically distinct GABA_B receptors. Although there is indirect evidence that certain GABA_B receptors may be more responsive to some agents than to others, there is no direct proof of molecularly or pharmacologically distinct sites. Because the neurotransmitter recognition site on the GABA_{B(1)} splice variants is identical, any difference in their responsiveness to a ligand is most likely due to an allosteric modification mediated by attachment of the

Figure 1 Structure and function of the GABA_B receptor. Attachment of GABA to the receptor recognition site located on the GABA_{B(1)} component causes dissociation of the α - and $\beta\gamma$ -subunits from the G-protein affiliated with the GABA_{B(2)} component of the receptor dimer. The liberated G-protein subunits influence cellular activity by regulating Ca^{2+} and K^{+} flux, adenylyl cyclase activity, and transcription factors. Reproduced from Enna S (2001) A GABA_B mystery: The search for pharmacologically distinct GABA_B receptors. *Molecular Interventions* 1: 208–218, with permission from American Society for Pharmacology and Experimental Therapeutics.

Figure 2 Chemical structures of some GABA_B-receptor agonists and a positive allosteric modulator.

agonist or antagonist to some portion of the receptor complex separate from the recognition site. The lack of evidence supporting pharmacologically distinct GABA_B-receptor subtypes has limited the clinical development of GABA_B-receptor agonists and antagonists because dose-limiting side effects accompany a generalized modification of GABA_B receptor function.

GABA_B-Receptor Agonists and Allosteric Modulators

Baclofen is the prototypical GABA_B-receptor agonist (Figure 2). In ligand-binding assays with rat brain membranes its affinity for the receptor is approximately 40 nM, with its EC_{50} values in functional assays being in the low- μM range. Baclofen has been employed for years as a treatment for spasticity associated with multiple sclerosis and spinal cord injuries, for nocturnal myoclonus, and for trigeminal neuralgia. It is the only GABA_B-receptor agent approved for clinical use.

A series of phosphinic acid analogs of GABA has yielded a number of potent and selective GABA_B-receptor agonists, including CGP 44532 and CGP 27492, which have been used for experimental purposes (Figure 2). Other compounds in this series include CGP 34938, the less-active (R)-(+)-enantiomer of CGP 34938, of which CGP 44532 is the more active (S)-(–) enantiomer, and SKF 97541, also known as CGP 35024. Rat brain membrane GABA_B-receptor-binding affinities for CGP 44532 and CGP 27492 are ~ 45 and 6.0 nM, respectively, with the corresponding values for CGP 44533 and SKF

97541 being 150 and 1.0 nM, respectively. Both tritiated baclofen and tritiated CGP 27492 are available as radioligands for labeling GABA_B receptors.

In vivo studies indicate that GABA_B agonists display sedative, muscle relaxant, and antinociceptive properties. They also impair memory performance, reduce the craving for cocaine, and can display both pro- and anticonvulsant activities. Tolerance develops to some of these responses upon repeated administration of agonist, and sedation precludes their use in many situations. Attempts to minimize these problems include modifications in the pharmacokinetic properties of baclofen preparations to enhance absorption and prolong duration of action.

As there are GABA_B receptors in the periphery, the therapeutic potential of GABA_B agonists is not limited to its actions in the CNS. For this reason, agents that do not cross the blood–brain barrier are being developed to treat conditions such as gastroesophageal reflux disease and pancreatic cancer.

Another approach to activating GABA_B receptors is with selective allosteric modulators, as exemplified by CGP 7930 (Figure 2). Modulators differ from conventional agonists in that they do not directly interact at the GABA_B-receptor-recognition site, but rather attach to some other portion of the receptor complex causing an allosteric modification in the neurotransmitter-binding site, or enhancing the efficiency of the receptor coupling with the effector system. Allosteric modulators, such as CGP 7930, GS 39738, and BHF177, increase both receptor affinity and the maximal response to the neurotransmitter. Certain arylalkylamines, some L-amino

Figure 3 Chemical structures of some GABA_B-receptor antagonists.

acids, and selected dipeptides have been proposed as GABA_B-receptor allosteric modulators, although these claims have been disputed. Nonetheless, because allosteric modulators indirectly influence receptor sensitivity by acting at a site distinct from that utilized by the neurotransmitter, such agents may be capable of distinguishing subtypes of GABA_B receptors, making it possible to more selectively modify this system for therapeutic gain.

GABA_B-Receptor Antagonists

The absence of selective receptor antagonists initially hindered the pharmacological characterization of the GABA_B site. The first antagonists developed for this purpose were phaclofen, a phosphonic acid analog of GABA, and saclofen, a sulfonic acid analog. Although both are highly selective as GABA_B-receptor antagonists, their affinities for this site are quite low, being greater than 100 μ M. Subsequently, a series of selective, high-affinity, and, in some cases, systemically active phosphinic acid derivatives were developed as GABA_B-receptor antagonists. Included in this group are CGP 54626 and CGP 62349 (Figure 3). Both of these compounds display K_d values at the GABA_B-binding site of 10 nM or less, and both have been radiolabeled for use as ligands for studying the localization, molecular properties, and pharmacological selectivity of this receptor. Other notable phosphinic acid GABA_B-receptor antagonists are CGP 36742, CGP 35348, CGP 55845, CGP 46381, and CGP 51176.

Morpholine derivatives have also been found to display GABA_B-receptor antagonist properties. This is exemplified by SCH 50911, a systemically active agent with a K_i of $\sim$ 300 nM at the GABA_B receptor (Figure 3).

Although no GABA_B-receptor antagonists have been approved for clinical use, laboratory animal studies suggest they may be effective in treating absence epilepsy, cognitive impairments, and affective illness. Clinical trials have been undertaken to examine their efficacy as treatments for cognitive impairments and depression.

Gastrointestinal Digestion and Absorption

J Keller, Israelitic Hospital, Hamburg, Germany

Introduction

Digestion and absorption of nutrients within the gastrointestinal tract require a complex interaction between secretory, motor, and absorptive functions, on the one hand, and between physical and biochemical events, on the other hand. Secretion of digestive enzymes starts in the oral cavity with salivary amylase, and nutrient digestion is continued in the stomach, mainly by the actions of gastric acid and pepsins. The pancreas delivers the most important and effective enzymes for macronutrient digestion. However, the final breakdown of oligosaccharides and oligopeptides takes place at the level of the brush border. While some drugs and potential constituents of human food, for example, urea and ethanol, may already be absorbed via the oral or gastric mucosa, the vast majority of nutrients are absorbed in the small intestine. Although nutrient digestion and absorption are extremely efficient in healthy humans, minor amounts are physiologically malabsorbed. These exert regulatory, mainly inhibitory effects on upper gastrointestinal secretory and motor activities and serve to nourish the colonic flora. The main function of the colon is absorption of water and electrolytes and under physiological circumstances the colon contributes little to overall calorie uptake. However, in case of carbohydrate malabsorption, colonic absorption of short-chain fatty acids that result from bacterial carbohydrate metabolism may salvage substantial amounts of nutrients that would otherwise be excreted with feces.

While nutrients are digested by secreted or membrane-bound enzymes and absorbed by the gastrointestinal mucosa, coordinated gastrointestinal motility is also one of the basic requirements for undisturbed and efficient digestion and absorption of a meal as well as excretion of indigestible residuals. Accordingly, milder motility disturbances can induce or contribute to symptoms such as diarrhea, constipation, and abdominal pain, severe motility disturbances may also impair nutrient absorption.

Digestive and absorptive mechanisms and in particular the regulation of the highly coordinated events that are needed for efficient digestion and absorption of meal nutrients are extremely complex. Thus, given the limitations of this article, it is impossible to give a detailed report of contemporary knowledge of each step of gastrointestinal digestion and absorption. Likewise, absorptive mechanisms responsible for micronutrient absorption, for example, the complex regulation of iron absorption and absorption of inorganic food components such as water and electrolytes will not be described in detail. Instead, this chapter will summarize what is currently known about the luminal and mucosal processes required for nutrient absorption with only brief reference to regulatory mechanisms and predominant limitation to human data. The article is organized in a way that the reader can follow the transit of a meal through the digestive tract. It serves to prepare the ground for the understanding and classification of the

information on individual nutrient components, the modes of action of specific enzymes, or dedicated metabolic pathways as described in other articles of this encyclopedia.

Mechanical and Enzymatic Breakdown of Nutrients in the Oral Cavity

In the oral cavity, ingested nutrients are fragmented by mastication and are mixed with saliva to form a food bolus that can easily be swallowed. The relevance of mastication for nutrition is illustrated by reduced appetite, weight loss, and increased mortality observed in people with chewing problems, especially edentulous subjects without dentures. The masticatory process appears to be crucial for optimal absorption of nutrients from some essential food components such as meat and vegetables but not from softer foods such as bread, cheese, rice, fish, and egg.

In addition to mechanical breakdown of food components, enzymatic digestion by salivary enzymes also starts within the oral cavity. The most important enzyme of saliva is α -amylase (molecular weight 54–57 kDa depending on the degree of glycosylation), which breaks carbohydrates (starches) down to maltoses by cleaving the α -1–4 glycosidic bonds. However, salivary α -amylase is rapidly inactivated at acidic pH in the stomach and therefore its contribution to carbohydrate digestion in healthy individuals is limited. Throughout the digestive period, salivary amylase comprises about 15% of total amylase output, the rest is attributable to pancreatic α -amylase. Autonomic nerve stimulation induces secretion of salivary α -amylase mainly from the parotid gland and to a lesser extent from the submandibular gland. In saliva, specifically collected from the parotid gland α -amylase may account for up to about one-third of the total protein content, while in mixed saliva the content is much lower. Since production and release of salivary α -amylase are controlled by the autonomic nervous system, there has been renewed interest in this enzyme as a surrogate marker of autonomic/sympathetic activity.

There is conflicting data whether in humans relevant amounts of lipolytic activity are secreted into saliva. While some researchers describe lipolytic activity in human tongue preparations, particularly in homogenates of the glandular region (Ebner) and in secretions collected from the trough of the papillae, this could not be confirmed by others. Anyway, there appear to be marked species differences with high activities of lingual lipase in homogenates of lingual serous glands from mouse and rat and only trace amounts in humans. Considering these levels of enzyme activity, it appears questionable whether lingual lipase has a physiological role in humans, at all.

While several drugs and some potential constituents of human food (e.g., urea) may be absorbed through the oral mucosa, oral absorption plays no relevant role for overall nutrient absorption in humans.

Esophageal Transport

The esophagus has no direct digestive function. The esophageal mucosa secretes low amounts of mucus that contains no enzymes but serves to facilitate the bolus transport and to protect the esophageal mucosa against acid and other aggressive components of gastroesophageal refluxate such as pepsin and potentially pancreatic enzymes. The main function of the esophagus is to transport ingested material to the stomach. During swallowing, coordinated activities of lingual and pharyngeal muscles transport the bolus toward the upper esophageal sphincter whereas the nasopharynx and larynx need to be occluded. The upper esophageal sphincter relaxes briefly in order to allow entrance of the bolus into the esophagus. Within seconds, it closes again and the bolus is then propelled downward through the tubular part of the esophagus which is formed by striated muscles in the upper third and by smooth muscles in the lower parts. At each time during the peristaltic wave, a segment several centimeters in length is contracted. The food bolus is always pushed several centimeters ahead of the zone of maximal contractility that is located in the middle of the contracted segment. In the distal part of the tubular esophagus, intraluminal pressure may rise physiologically to up to 180 mmHg. Normal propagation velocity of the peristaltic wave ranges from 2 to 8 cm s⁻¹. The lower esophageal sphincter, which normally maintains a resting pressure of about 15–30 mmHg that serves to prevent reflux of gastric contents, relaxes before the peristaltic wave arrives and, thus, lets the bolus pass into the stomach.

Gastric Functions

The stomach has important motor, secretory, and digestive functions, while gastric absorption of food components only plays a marginal role.

Gastric Transit of a Meal

Food ingestion induces a vagally mediated reflex which relaxes the proximal stomach; arrival of food into the stomach enhances this process of accommodation so that a meal can be ingested without inducing increased intragastric pressure or tension that would cause nausea and discomfort. During the early postprandial period, solid food is retained in the proximal part of the stomach. By contrast, liquids are distributed more widely within all of the stomach. The pylorus maintains only a small opening area throughout the digestive period. This allows rapid gastric emptying of liquids. However, with increasing calorie content of the liquid phase of a meal, there is a deceleration from an exponential to a more linear-emptying pattern induced by inhibitory duodenal feedback mechanisms. The release of cholecystokinin from duodenal enterochromaffin cells likely plays a major role not only for prandial inhibition and regulation of gastric emptying but also for integration of digestive upper gastrointestinal functions (Figure 1).

Solids are retained selectively and undergo trituration by antral contractions as they are propelled toward the almost closed pylorus. Acid and peptic digestion of meal components supports this process. Digestible food particles are emptied into the duodenum after their size has been reduced to about 2 mm. Under physiological circumstances, gastric emptying of nutrients takes place at a rate of 2–3 kcal min⁻¹. In consequence, complete gastric emptying of a regular meal approximately takes 3–4 h. Food components that cannot be reduced to small pieces remain within the stomach and are emptied into the duodenum at the very end of the digestive period when the fasting motility pattern (phase III-motility) recurs.

Gastric Secretory and Digestive Functions

Gastric motility does not only serve to grind solids and to transport gastric contents toward the duodenum but also

Figure 1 Nutrients within the duodenal lumen, in particular, free fatty acids (FFA) and specific essential amino acids (EAA), release cholecystokinin (CCK) from enterochromaffin cells of the mucosa. CCK exerts inhibitory effects on gastric emptying and at the same time stimulates pancreatic enzyme secretion, gall bladder contraction, and digestive small intestinal motility. Accordingly, gastric chyme is delivered in small portions to the duodenum with simultaneous supply of large amounts of digestive enzymes and biliary secretions and extensive mixing of chyme and slow aboral transit.

mixes the food with gastric secretions, and, thus, improves digestion.

Digestive role of gastric secretions

Gastric acid secretion and intragastric pH

Hydrochloric acid is the main component of gastric juice and is secreted by the parietal cells of the gastric mucosa in the fundus and corpus. In healthy adults, intragastric pH ranges between 1.5 and 2.5 in the fasting state. Intragastric nutrients are the most potent stimulators of gastric acid secretion; however, due to dilution and buffering effects there is usually a transient rise in gastric pH postprandially to values between 4.5 and 6.0. Extent and duration of the rise in pH depend not only on meal properties but also on gastric-emptying velocity. Mean postprandial hydrochloric acid output is about 20–30 mmol h⁻¹.

Gastric protein digestion

Gastric secretions facilitate the digestion of protein which commences in the stomach by acid denaturation and hydrolysis by gastric proteases or pepsins. These enzymes are secreted by gastric mucosal cells in precursor form (pepsinogens) and are activated by exposure to acid and autocatalysis. Pepsins are endopeptidases that cleave internal peptide bonds, in particular those adjacent to hydrophobic amino acids.

Gastric acid secretion and absorption of micronutrients

While gastric secretions contribute to protein digestion, gastric acidity improves iron absorption. Gastric acid specifically facilitates the dissociation of iron salts from food. Gastric acid also reduces ferric iron to the more soluble ferrous form and allows formation of complexes with ascorbate, sugars, and amines. These further enhance iron absorption in the duodenum.

Moreover, absorption of minerals in the small intestine usually requires soluble molecules. Gastric acid can release minerals, almost exclusively cations, from organic food matrices. Since solubility of positively charged ions is higher in more acidic solutions, gastric acid improves absorption of minerals. In particular, gastric acid transforms the relatively insoluble calcium salts (e.g., calcium carbonate) to more soluble forms and thus facilitates calcium absorption.

Vitamin B 12 ingested with meals is bound to food proteins. The vitamin needs to be released from these proteins and then bound to R-proteins and intrinsic factor in order to be absorbed in the terminal ileum. Gastric acid and pepsin facilitate the proteolytic process involved in releasing the vitamin from the proteins in ingested food. Accordingly, short-term treatment of healthy subjects with an acid-suppressive drug (proton pump inhibitor) was associated with a more than 70% reduction of vitamin B 12 absorption. Long-term studies in patients have shown that vitamin B 12 concentrations remain within the normal limit within the first 3 years of treatment, whereas a longer duration of therapy was associated with a small but significant downward trend.

Impairment of vitamin C absorption in case of decreased gastric acid secretion is less well established. However, it has been shown that treatment with proton pump inhibitors may produce a slight reduction in the serum concentration of vitamin C. This was attributed to the relative instability of vitamin C at higher pH and luminal metabolism to 2,3-diketogulonic acid which cannot be converted back to bioactive vitamin C.

Gastric lipase

Pepsins are not the only enzymes that are produced by the gastric mucosa in humans. In addition, gastric lipase is secreted by the chief cells of the fundus in response to neurohormonal stimuli elicited by food intake, in particular, gastrin and cholinergic mechanisms, and inhibited by cholecystokinin and glucagon-like peptide-1. It has been estimated that 10–20% of meal triglycerides may be hydrolyzed by gastric lipase, with diacylglycerol and free fatty acids as the main metabolites. This mechanism is essential for digestion of human milk fat globules in newborn infants. By contrast, in healthy adults, the physiological role of gastric lipase may be rather regulatory than quantitatively contributing to overall lipid digestion: enhanced intragastric emulsification and predigestion of dietary fat results in early postprandial duodenal delivery of free fatty acids as the most potent stimulators of postprandial pancreatic enzyme secretion.

Digestion and Absorption of Nutrients in the Small Intestine

Intestinal Transit of Meal Nutrients

The transportation rate of the small intestine is comparable to that of the stomach. Mainly due to faster gastric emptying, liquids typically arrive in the colon before solids and the head of the column of liquid chyme may pass the small intestine and reach the cecum within 30 min after oral ingestion. However, it takes much longer, namely about 2.5 h for half the liquid chyme to traverse the small bowel, and after grinding of solid components, intestinal transit time appears to be similar for solid and liquid food components.

The proximal small intestine absorbs nutrients extremely efficiently: Following perfusion of nutrients into the proximal duodenum at physiological postprandial rates, about 80% of triglycerides, 60% of carbohydrates, and 50% of proteins have been shown to be absorbed before reaching the distal duodenum 20 cm apart. However, even in healthy humans small amounts of nutrients are not absorbed during small intestinal transit but reach the terminal ileum and are delivered to the colon. The extent of this so-called physiological malabsorption depends on type and preparation of a meal. With the exception of starch from rice, most complex carbohydrates result in malabsorption rates of about 10%. Lipid malabsorption may reach 5% of the amount administered. Physiologically malabsorbed nutrients do not only serve as energy source for colonic bacteria but also exert regulatory, mainly inhibitory effects on upper gastrointestinal functions (ileal brake mechanism) and, thus, likely contribute to restitution of the interdigestive secretory and motor pattern at the end of the digestive period. Glucagon-like peptide-1 and peptide YY are important neurohormonal mediators implicated in the ileal brake mechanism in humans.

Irregular, partly segmental, partly propagated contractions of the small intestinal wall induce slow aboral transport of chyme and are also responsible for extensive mixing of nutrients with digestive secretions and distribution of chyme over the mucosal surface. Intestinal motility is based on contractions of intestinal smooth muscle cells. However, coordinated motility also requires a complex regulation by neurohormonal mediators, particularly via the enteric nervous system, the

brain–gut axis, and gastrointestinal peptide hormones. These regulatory mechanisms provide the coordination of smooth muscle cells among themselves, with secretory and absorptive functions of the gastrointestinal tract and with the superordinate requirements of the body.

Intestinal pH

The chyme that reaches the duodenal bulb in small portions usually has an acidic pH. Both, the pancreatic duct and the common bile duct lead into the proximal duodenum at the Papilla of Vater, and, mainly due to bicarbonate secretion from the pancreas and to a far lesser extent from biliary secretions or from the intestinal mucosa itself, the pH in the descending duodenum is maintained at a considerably higher level. The pH of aspirates from the distal duodenum of healthy subjects is 6–7 in the fasting state. Following ingestion of a normal meal, duodenal pH is around 6 early postprandially, drops toward 5–5.5 during the second and third postprandial hour, and reaches preprandial values at the end of the digestive period. The high duodenal pH is a prerequisite for efficient digestion of complex carbohydrates, proteins, and lipids because all pancreatic enzymes have their pH optima in the alkaline range. Lipase in particular is even irreversibly destroyed at pH levels below 4.

Due to impaired accessibility of the more distal parts of the human small intestine, pH profiles of the jejunum and the ileum are less well established. However, it has been shown that pH increases toward pH 7–8 and is more stable in the distal small intestine.

Pancreatic Exocrine Secretion

Sufficient absorption of macronutrients to maintain energy supply depends on prior hydrolysis by pancreatic enzymes. Thus, untreated complete lack of pancreatic enzymes (e.g., due to pancreatectomy) is not compatible with life. Normally, however, in healthy individuals, the cumulative postprandial pancreatic enzyme response exceeds by far (10–15-fold) the quantity required to prevent overt maldigestion. Depending on nutrient intake, about 3 l of pancreatic juice are secreted into the duodenum per day. The most important inorganic components of pancreatic juice apart from bicarbonate are water, potassium, and chloride. Moreover, pancreatic juice contains high amounts of hydrolytic enzymes or their precursors for digestion of complex carbohydrates, proteins, and lipids. The most important ones are α -amylase, trypsin and chymotrypsin, lipase, and colipase. Furthermore, elastases, carboxypeptidases, phospholipase A₂, carboxylesterase lipase, and ribo- and deoxyribonucleases are also secreted. Some of the enzymes such as trypsinogen are present in more than one form (cationic and anionic form). Proteases enter the duodenum as inactive zymogens; trypsinogen is then partly converted to trypsin by the duodenal enzyme enterokinase. Subsequently, trypsin exerts an autocatalytic effect and also activates the other proteases (Figure 2). In contrast to proteases, α -amylase and lipase are secreted in active form.

Like the other gastrointestinal organs, the pancreas is not inactive during the fasting state but maintains a cyclical secretory pattern with maximal interdigestive secretion rates at

Figure 2 The pancreatic enzyme cascade: pancreatic proteases enter the intestinal lumen as inactive zymogens. Within the duodenum a specific enzyme of the duodenal mucosa, enterokinase, activates trypsinogen by releasing the trypsinogen activation peptide (TAP). Subsequently, active trypsin activates the other zymogens and acts autocatalytically.

about 2-h intervals that is closely coordinated with gastrointestinal motor functions. However, in response to ingestion of a regular meal, enzyme output increases considerably with a short phase of maximal enzyme secretion. This means a three- to sixfold increase above interdigestive levels of all major enzymes. Overall, maximal postprandial outputs reach about 3–6 kU min^{−1} for lipase, 0.5–1 kU min^{−1} for amylase, and 0.2–1 kU min^{−1} for trypsin. Thereafter, 2–4 kU min^{−1} of lipase, 0.5 kU min^{−1} of amylase, and 0.15–0.5 kU min^{−1} of trypsin are stably released into the duodenum for 2 h or longer. Late postprandially, secretory rates return to the interdigestive range. Both, degree and duration of the digestive enzyme response are determined by the caloric content, nutrient composition, and physical properties of a meal. Meals containing at least about 500 kcal induce maximal enzyme responses. Lipids are the strongest stimulants of pancreatic enzyme secretion, but, in humans, duodenal free fatty acids rather than triglycerides appear to be responsible for release of cholecystokinin from the duodenal mucosa which in turn stimulates enzyme output. The stimulatory potency of proteins is limited to specific essential amino acids (phenylalanine, valine, methionine, and tryptophane). Carbohydrates are the weakest stimulants.

Following submaximal digestive stimulation by a test meal devoid of exogenous proteins, cumulative postprandial duodenal protein delivery mainly represents pancreatic enzyme output and was demonstrated to be about 5 g. Maximal duodenal protein delivery was achieved 1 h postprandially and reached 30 g min^{−1}.

The most important stimulatory hormones are cholecystokinin and secretin. Both are peptide hormones which are produced and released by the enterochromaffin cells of the proximal small intestinal mucosa. Cholecystokinin is the strongest physiological stimulator of enzyme secretion. By contrast, secretion of bicarbonate is predominantly stimulated

by secretin which is released in response to duodenal acid exposure. Apart from this, vagal efferents are important regulators of both, enzyme and bicarbonate secretion. Moreover, in humans, part of the hormonal effects appear to be mediated via receptors on vagal nerve fibers instead of receptors on pancreatic cells.

Late postprandially, stimulatory mechanisms caused by nutrients in the proximal small bowel and inhibitory mechanisms induced by nutrient exposure of the distal small bowel (ileal brake mechanism) seem to interact to coregulate pancreatic exocrine secretion during the functional interface between the late postprandial and the subsequent interdigestive period.

Bile Acid Secretion and Absorption

In parallel with pancreatic secretion, basal bile acid output (about 10–20 mmol min⁻¹) is increased markedly by meal ingestion (three- to sixfold) leading to a short-lived peak of bile acid output followed by a period of stable or slowly declining biliary secretion. Bile acids are produced by the liver and represent the water-soluble end products of cholesterol metabolism. After their synthesis from cholesterol, they are conjugated with glycine or taurine. This conjugation makes them impermeable to cell membranes; in consequence, high concentrations are achieved in bile and intestinal chyme. Bile acids are secreted into the proximal duodenum and absorbed actively from the terminal ileum by the so-called apical bile salt transporter (sodium-dependent cotransporter) and a basolateral transporter (anion exchanger). According to animal studies, there may be a second transporter in the proximal small intestine that transports dihydroxy-conjugates preferentially. Each bile acid molecule undergoes multiple enterohepatic circulations before it is finally excreted. Unconjugated bile acids formed by bacterial deconjugation are passively absorbed in the distal intestine and promote diarrhea.

Lipid Digestion and Absorption

Triglycerides

Long-chain triglycerides are the most important dietary lipids. Their digestion depends on an intricate interplay among pancreatic lipase, colipase, and bile acids. Pancreatic lipase hydrolyzes a triglyceride molecule to two fatty acid molecules and 2-monoacylglycerol. For this, lipase binds to the oil–water interface of oil droplets. Both, bile acids and colipase are important to achieve its full lipolytic activity: Bile acids support the emulsification of triglycerides and form micelles with fatty acids and monoglycerides to remove them from the oil–water interface. Colipase forms a complex with lipase in the presence of bile salts. This complex anchors lipase and allows its action in a more hydrophilic environment. Further, hydrolysis of a minor fraction of the 2-monoacylglycerol molecules by pancreatic lipase can result in the formation of glycerol and free fatty acids; cholesterol esterase can also hydrolyze the acyl group at the *sn*-2 position to form the same end products.

Long-chain free fatty acids and 2-monoacylglycerol are absorbed after incorporation into micelles. A protein-independent diffusion model and protein-dependent mechanisms have been proposed for the uptake and transport of fatty acids across

the apical membrane of the enterocyte. Within the enterocytes, the products of intraluminal triglyceride digestion are resynthesized to form triglycerides before they are transported to the liver.

Triglyceride digestion in healthy humans is highly efficient and up to 80% of lipids may be absorbed during duodenal transit, that is, even before reaching the ligament of Treitz. In exocrine pancreatic insufficiency, on the other hand, elevated fecal fat excretion is only expected if prandial secretory rates are less than 5–10% of normal.

Phospholipids

Phosphatidylcholine is the predominant phospholipid in the lumen of the small intestine. Phospholipids are digested by pancreatic phospholipase A2 and other pancreatic lipases. These interact with phospholipids at the *sn*-2 position to yield free fatty acids and lysophosphatidylcholine. These metabolites are removed from the water–oil interface when they are incorporated into the mixed micelles.

Cholesterol

Cholesterol in the intestinal lumen is derived from both, endogenous sources and dietary sources: The human diet provides about 400 mg of cholesterol daily, and the liver secretes 1 g daily. About 50% of the cholesterol in the intestine is absorbed; the remainder is excreted with feces. Most dietary cholesterol exists in the form of the free sterol, with only 10–15% existing as the cholesteryl ester. The latter must be hydrolyzed by cholesterol esterase to release free cholesterol for absorption. Moreover, cholesterol must pass through a diffusion barrier at the intestinal lumen–enterocyte membrane interface before it can interact with the transporter proteins responsible for its uptake and subsequent transport across the cellular brush border. Bile salt micelles facilitate the transfer of cholesterol across the unstirred water layer. Thus, cholesterol absorption depends on the presence of bile acids in the intestinal lumen.

Protein Digestion and Absorption

Digestion of dietary and endogenous proteins by pepsins and pancreatic proteases produces small polypeptides and free amino acids; these are further hydrolyzed by brush border peptidases. Absorption mainly takes place in the proximal jejunum but other parts of the small intestine also have significant transport capacity. The transport into the enterocytes occurs by major active carrier transporters for neutral, dibasic, and dicarboxylic amino acids.

Small peptides consisting of 2 or 3 amino acids can be absorbed across the apical membrane of the enterocytes lining the small intestine via the proton-driven peptide transporter PEPT-1. Small peptides are then mostly broken down intracellularly into single amino acids. However, intact polypeptides can also be transported across the enterocyte membrane. Thus, in individuals with amino acid transport defects, peptide absorption can be normal. The nutritional importance of oligopeptide absorption may be considerable because the total absorption of amino-nitrogen is greater from such peptides that are more rapidly absorbed than amino acids even in diseased intestine.

Gastric acid suppression therapy hampers protein assimilation. However, the relative importance of gastric protein digestion (by acid and pepsin) is generally thought to be limited because of the high proteolytic activity delivered by the pancreas. Conversely, decreased pancreatic protease secretion may partly be compensated by gastric and small intestinal compensatory mechanisms.

Carbohydrate Digestion and Absorption

Dietary carbohydrate is also predominantly absorbed within the proximal small intestine. Before small intestinal absorption can occur, complex carbohydrates need to be hydrolyzed by salivary and pancreatic amylases to glucose, maltose, maltotriose, and oligosaccharides. Together with dietary disaccharides (mainly sucrose and lactose), these metabolites are further hydrolyzed by the brush border enzymes maltase, sucrase-isomaltase, and lactase resulting in monosaccharide production. Luminal monosaccharides such as glucose and galactose are transported by carrier-mediated mechanisms across the enterocyte brush border. Up to 50% of this transport depends on a sodium ion gradient. This active process requires the presence of a sodium gradient between the exterior and interior of the cells. The low intracellular sodium concentration is maintained by the basolaterally located Na-K-adenosine triphosphatase, which extrudes accumulated sodium. Transport of sodium ions down their electrochemical gradient provides the driving force for glucose cotransport and allows the uptake of glucose from a low extracellular concentration into the cells. The main sodium-glucose cotransporter present in the human intestine is SGLT-1.

Apart from this, five functional mammalian-facilitated hexose carriers (GLUTs) have been characterized by molecular cloning. Of these, three are high-affinity transporters (GLUT-1, GLUT-3, and GLUT-4) and one is a low-affinity transporter (GLUT-2) for glucose. GLUT-5 is primarily a fructose carrier. The expression of these transporters is regulated by glucose and several hormones. The transporters most relevant to monosaccharide absorption in the intestine are GLUT-2 and GLUT-5, which support facilitated rather than active transport.

Contribution of the Colon to Nutrient Absorption

Under physiological circumstances, the colon contributes very little to overall nutrient absorption. By contrast, in states of carbohydrate malabsorption, such as severe pancreatic exocrine insufficiency or short bowel syndrome, the colon can become a significant source of energy salvage: Up to about 80% of carbohydrates not absorbed by the small bowel can be absorbed after bacterial metabolism to short-chain fatty acids and thus contribute markedly to energy supply (500–1000 kcal).

Glossary

Intrinsic terminator A signal in the nascent RNA transcript that signals RNA polymerase to halt transcription and dissociate from the DNA template. Intrinsic terminators consist of a short base-paired stem-loop structure followed by a short stretch of U residues in the RNA. Also called factor-independent terminator or Rho-independent terminator.

Ribosome The large RNA-protein complex that translates messenger RNA (mRNA) into protein. It consists of two subunits, termed small and large.

RNA polymerase (RNAP) The enzyme that transcribes DNA into RNA. In bacteria, there is only one version of this enzyme.

Transcriptional pausing In response to signals in the RNA, RNAP will pause and discontinue transcription but not dissociate from the DNA template. Either after some period of time, or in response to a signal, a paused RNAP will resume transcription.

Transfer RNA (tRNA) The adaptor RNA molecule that reads the genetic code in the mRNA by base pairing with the codon triplets. An amino acid is attached to the 3' end of the last base in the tRNA by an enzyme called an aminoacyl tRNA synthetase in a process called 'aminoacylation' or 'charging'. There are tRNAs corresponding each of the 20 amino acids.

Transcription attenuation is defined as any mechanism that utilizes transcriptional pausing or termination to control expression of downstream genes. This mechanism of regulation is used to control expression of many genes in bacteria in responses to changes in their environment. Moreover, bacteria have evolved several elaborate and elegant variations on the attenuation theme, mainly based on the mechanism used to control formation of the RNA structures that signal RNA polymerase (RNAP) to pause or terminate transcription.

Attenuation

The first attenuation mechanism to be thoroughly described was that which controls transcription of the *Escherichia coli* tryptophan biosynthetic (*trpEDCBA*) operon. When Charles Yanofsky and co-workers elucidated this mechanism, it was the first demonstration that organisms can utilize changes in RNA structure to regulate gene expression. Subsequently, many other examples of transcription attenuation have been discovered. In each case, the *cis*-acting genetic information is contained within a 150–300-base region of RNA located after the start of transcription and prior to the start of the coding sequence for the first structural gene of the operon. This segment of RNA is called the leader region but is analogous to 5' untranslated regions (5'UTRs) seen in many eukaryotic messenger RNAs (mRNAs). The article illustrates the features of transcription attenuation control of the *E. coli trp* operon and then describes the variations to this classic system that allow attenuation to be adapted to control other amino acid biosynthetic operons, then goes on to describe attenuation control of the *trp* operon in the Gram-positive bacterium *Bacillus subtilis*, which involves larger variations on the attenuation theme. There are several recent reviews that cover the attenuation in more depth as well as describe attenuation control of other bacterial genes.

The *E. coli trp* Operon: Attenuation Based on Translation of a Leader Peptide

The *E. coli trpEDCBA* operon encodes the enzymes required to synthesize *L*-tryptophan from chorismic acid. Transcription of the *trp* operon is regulated in response to changes in the levels of tryptophan inside the cell. When cells contain adequate amounts of tryptophan, for example, when it is present in the growth medium, transcription of the operon is downregulated. By contrast, when the cell has low levels of tryptophan, the *trp* operon is actively transcribed in order to express the enzymes required for synthesizing more. Initiation of transcription is regulated by the *trp* repressor, a DNA-binding protein encoded by the *trpR* gene. In addition, after transcription has initiated, the elongating transcription complex is subject to regulate by attenuation. Together, repression (80-fold) and attenuation (eightfold) serve to allow approximately 600-fold overall control of transcription of the *trp* operon in response to various levels of tryptophan availability.

Attenuation Control of the *E. coli trp* Operon

The *E. coli trp* operon contains a 162-nucleotide leader region prior to the start of the *trpE* coding sequence. There are several inverted repeats in the *trp* leader mRNA transcript, which are composed of the segments labeled 1–4 in Figure 1. These segments can base-pair to form three different overlapping base-paired RNA secondary structures (Figure 1). These structures include an intrinsic transcription terminator (3:4), an overlapping antiterminator (2:3), and a pause structure (1:2). In addition, the leader transcription contains a small open reading frame (ORF), which encodes a 14-amino-acid leader peptide. There are two critical tandem UGG Trp codons within this ORF. How efficiently these two Trp codons can be translated determines which RNA structure forms in the nascent leader transcript, which in turn controls whether transcription

Figure 1 Model of transcription attenuation of the *E. coli trp* operon. RNA polymerase pauses following formation of the pause structure. This provides time for a ribosome to initiate translation of the leader peptide. Under tryptophan limiting conditions, the ribosome stalls at the tandem Trp codons, resulting in transcription read through. Under conditions of tryptophan excess, the ribosome reaches the leader peptide stop codon. This ribosome position blocks formation of the antiterminator leading to terminator formation and transcription termination.

halts in the leader region or continues into the structural genes of the operon.

Shortly after transcription initiates from the *trp* promoter, the 1:2 pause hairpin forms in the nascent RNA (Figure 1). This structure signals RNAP to suspend transcription after nucleotide 92. Pausing of RNAP is a critical feature of the attenuation mechanism because it allows time for a ribosome to initiate translation of the leader peptide. When a ribosome begins translating the leader peptide, this releases the paused RNAP to resume transcription. Transcription and translation are now coupled, with the ribosome closely following RNAP. This situation is essential to allow events involving the ribosome to affect transcription by the associated RNAP.

At this point, there are two possible pathways for the attenuation mechanism to follow depending on the level of tryptophan in the cell. The choice depends on how efficiently the tandem Trp codons in the leader peptide are translated. This efficiency reflects the availability of aminoacylated $tRNA^{Trp}$ in the cell. Under conditions where tryptophan is limiting, the

amount of charged $tRNA^{Trp}$ is low. As a result of the low concentration of tryptophanyl- $tRNA^{Trp}$, translation of the tandem Trp codons is inefficient and the ribosome stalls at one of these two codons. The associated RNAP continues to transcribe through the *trp* leader region and transcription and translation become uncoupled. As RNAP continues transcribing through segments 2 and 3 of the leader region, the antiterminator structure (2:3) forms, which prevents formation of the overlapping intrinsic terminator (3:4) structure. Hence, transcription continues through the leader region and into the structural genes of the operon which encode the tryptophan biosynthetic enzymes.

When tryptophan is plentiful, the level of charged $tRNA^{Trp}$ in the cell is high. This situation allows efficient translation of the tandem Trp codons and hence the ribosome proceeds rapidly to the end of the leader peptide. When the ribosome reaches the leader peptide stop codon, it covers part of RNA segment 2 and prevents formation of the 2:3 antiterminator structure as transcription proceeds. Thus, RNA segment 3 is free to base-pair with segment 4 and form the transcription

terminator. Under these conditions, transcription terminates in the leader region prior to the *trp* structural genes, which are therefore not expressed.

In this attenuation mechanism the regulatory signal is the level of aminoacylated tRNA^{Trp} and the sensory event is the efficiency with which the ribosome can translate the tandem UGG Trp codons in the leader peptide. This system can easily be adapted to regulate other amino acid biosynthetic operons. The only modification that is needed is to change the identity of the critical codons in the leader peptide, which controls the response of the system to a specific amino acid. There are numerous examples of such adaptations of this attenuation mechanism, particularly in enteric bacteria, including the *his*, *phe*, and *leu* operons, which contain seven His, seven Phe, and four Leu codons in their respective leader peptides.

The *B. subtilis trp* Operon: Attenuation Mediated by an RNA-Binding Protein

The transcription attenuation mechanism that regulates the *trp* operon in the Gram-positive bacterium *B. subtilis* differs more dramatically from that of the *E. coli trp* operon than those described above for other amino acid biosynthetic operons in Gram-negative bacteria. Most notably there is no leader peptide, and ribosomes are not involved in this attenuation mechanism. Instead, an RNA-binding protein senses the level of tryptophan in the cell and determines whether transcription terminates in the leader region or continues into the structural genes.

The *B. subtilis trp* Leader

Expression of the *trpEDCFBA* operon in *B. subtilis* and related bacteria is regulated by the *trp* RNA-binding attenuation protein (TRAP). Transcription of the operon initiates from the *trp* promoter 203 nucleotides upstream of the start codon of the first structural gene, *trpE* (Figure 2). There is no evidence for any regulation of initiation of transcription from this promoter. Hence, there is no homolog, either functional or based on amino acid sequence, of the DNA-binding *trp* repressor from *E. coli* in *B. subtilis*. The *B. subtilis trp* leader transcript contains inverted repeats that can form an intrinsic transcription terminator (C:D) and an antiterminator (A:B) RNA secondary structure (Figure 2). These two structures overlap by four nucleotides and hence their formation is mutually exclusive.

In the presence of excess tryptophan, TRAP binds to a series of 11 trinucleotide repeats in the *trp* leader transcript consisting of seven GAGs and four UAGs (Figure 2). These (G/U)AG repeats are separated from each other by two or three spacer nucleotides, whose sequence is not conserved. The triplet repeats partially overlap the 5' portion of the antiterminator structure and hence TRAP binding interferes with formation of the antiterminator (A:B) thus favoring formation of the terminator (C:D) hairpin. Therefore, under these conditions, transcription halts in the leader region prior to the *trp* structural genes, which are not expressed.

When tryptophan is limiting, TRAP does not bind to the *trp* leader RNA, and hence formation of the A:B antiterminator is favored. This situation allows transcription to continue into the *trp* operon structural genes, which can now be expressed to produce the enzymes to synthesize tryptophan.

Figure 2 Model of transcription attenuation of the *B. subtilis trpEDCFBA* operon. The large blue letters indicate the complementary strands of the terminator and antiterminator RNA structures. The TRAP protein is shown as a ribbon diagram with each of the 11 subunits as a different color and the bound RNA is shown forming a matching circle upon binding to TRAP. The bound tryptophans are shown as space filling models. The GAG and UAG repeats involved in TRAP binding are shown in ovals and are also outlined in the sequence of the antiterminator structure. Numbers indicate the residue positions relative to the start of transcription. Nucleotides 108–111 overlap between the antiterminator and terminator structures and are shown as darkly outlined letters.

The TRAP Protein

In this system, the basis for attenuation control is the ability of TRAP to sense the level of intracellular tryptophan and then to influence the structure of the nascent *trp* leader mRNA transcript. TRAP is a ring-shaped protein composed of 11 identical subunits (Figure 3). TRAP is activated to bind its RNA targets by binding 11 molecules of *L*-tryptophan in clefts between adjacent subunits. The detailed mechanism by which tryptophan binding activates TRAP to bind RNA is not known; however, it is clear that the protein is an 11mer in the absence or presence of bound tryptophan. Recent studies have shown that tryptophan binding induces a conformational change in TRAP as well as reduces the flexibility of the protein.

Upon activation by tryptophan, TRAP binds to its RNA target consisting of the 11 (G/U)AG repeats by wrapping the single-stranded RNA around the outer perimeter of the protein ring (Figure 3). The phosphodiester backbone is on the outside of the RNA ring and the bases point in toward the protein. The specificity of this interaction derives from hydrogen bonds between Glu36, Lys37, Lys56, and Arg58 of each TRAP subunit and the bases on the (G/U)AG repeats. The spacer nucleotides between the triplet repeats do not contact the protein, and their identity is not crucial for TRAP recognition and binding. This mechanism of wrapping the RNA around the protein ring explains both the specificity of the TRAP–RNA interaction as well as how TRAP binding alters the structure of the *trp* leader RNA to regulate attenuation.

The Role of Timing in TRAP-Mediated Attenuation

As described above for the *E. coli trp* attenuation system, the timing of altering the folding of the leader region RNA is crucial for proper regulation of transcription. In this case, TRAP must bind to its target and induce formation of the transcription terminator before RNAP transcribes beyond the terminator segment of the leader region. If TRAP binds too late,

altering the folding pattern of the RNA will not influence the activity of the transcribing RNAP. There are several features of the *B. subtilis trp* system that serve to ensure proper timing of the regulatory factors.

There are several features of the *trp* attenuation system that allow TRAP to bind to the nascent transcript early during transcription of the leader region, before all of the 11 triplet repeats of the binding site are exposed from RNAP. The first feature is the multi-subunit nature of TRAP combined with the multiple small repeated elements in the RNA binding site. TRAP has been shown to bind with high affinity to RNAs with as few as 4–5 (G/U)AG repeats. In addition, an RNA hairpin forms at the 5' end of the *trp* leader mRNA (Figure 2, 5'SL), which influences TRAP binding to the RNA. The presence of the 5'SL increases the affinity of TRAP for the leader region RNA when fewer than the full complement of 11 triplets have been synthesized.

Recent studies also show that RNAP pauses at U107 (Figure 2) during transcription of the *trp* leader region, and that this pausing is dependent on the NusA transcription factor. This pause provides additional time for TRAP to bind to the nascent *trp* leader RNA and promote termination.

Figure 3 Ribbon diagram of TRAP complexed with an RNA containing 11 GAG repeats separated by AU spacers. The TRAP protein is shown in ribbon diagrams with each subunit depicted in a different color. The RNA is shown in stick models and the 11 molecules of bound *L*-tryptophan are shown in space filling models.

Figure 4 Ribbon diagram of anti-TRAP (AT) and AT in complex with TRAP. The proteins are shown as ribbon with each subunit depicted in a different color. The 11 molecules of *L*-tryptophan bound to TRAP and the zinc atoms bound to AT are shown in space filling models.

Anti-TRAP and the Role of tRNA^{Trp} in Regulating the *B. subtilis trp* Genes

In the *B. subtilis trp* attenuation system, the regulatory signal is the level of the amino acid tryptophan free in the cell, which activates TRAP to bind RNA. In the previously described *E. coli trp* attenuation system, free tryptophan is sensed by the DNA-binding *trp* repressor protein and the regulatory signal for attenuation is the availability of aminoacylated tRNA^{Trp}. The level of charged tRNA^{Trp} also influences attenuation control of the *B. subtilis trp* operon, although by a very different mechanism than in the *E. coli* system. In *B. subtilis*, the *rtpA* gene encodes a protein called anti-TRAP (AT) (Figure 4). AT influences expression of the *trp* genes by binding to tryptophan-activated TRAP and preventing it from binding RNA, thus elevating expression of *trp* genes. Transcription of *rtpA*, which is in a two-gene operon together with *ycbK* (unknown function), is regulated in response to changes in the level of uncharged tRNA^{Trp} by a mechanism known as T-box antitermination. High levels of uncharged tRNA^{Trp} induce transcription of AT, which prevents TRAP from downregulating expression of the *trp* genes.

Translation of *rtpA* is also regulated in response to the level of aminoacylation of tRNA^{Trp}. This regulation is based on the cells' ability to translate a 10-codon leader peptide sequence located just upstream from the *rtpA* gene. The leader peptide-coding segment contains three consecutive Trp codons. If there is insufficient aminoacylated tRNA^{Trp} to allow efficient translation, the translating ribosome stalls at one of these three Trp codons. This situation exposes the ribosome-binding site for the *rtpA* gene and allows efficient translation of rtpA. However, if there is sufficient charged tRNA^{Trp} to allow efficient translation of rtpLP, when the ribosome reaches the stop codon, its presence blocks the ribosome-binding site for *rtpA* and inhibits translation initiation at the *rtpA* start codon.

Together, these systems ensure that even if free tryptophan levels are high enough to activate TRAP, if the level of charging of tRNA^{Trp} is low, then the *trp* genes will be expressed. Thus,

while both *E. coli* and *B. subtilis* regulate expression of the *trp* genes in response to changes in levels of both free tryptophan and aminoacylated tRNA^{Trp}, they have evolved very different mechanisms to do so.

Occurrences of TRAP-Mediated Attenuation in Bacteria

TRAP-mediated attenuation control of the *trp* operon has to date been observed mainly in low GC Gram-positive bacteria and some related species. In contrast to the leader-peptide-dependent mechanism described previously, the RNA-binding protein-dependent attenuation mechanism has never been characterized for any other amino acid biosynthetic operons, besides tryptophan, even though it would seem to be easily adaptable by simply changing the amino acid that activates the protein to bind its RNA target. Perhaps with the explosion of bacterial genomic information currently becoming available, we will soon discover such a system.

Architecture

A 10-polypeptide polymerase II (Pol II) core enzyme is sufficient to elongate the RNA transcript. For transcription initiation, an additional two-subunit Rpb4/7 complex and several general transcription factors are required. In the crystal structures of the complete 12-subunit Pol II, the two large subunits, Rpb1 and Rpb2 (Table 1), form the central mass of the enzyme, and opposite sides of a positively charged cleft that contains the active center (Figure 1). The two large subunits are bridged on one side by a module of subunits Rpb3, Rpb10, Rpb11, and Rpb12. Around the periphery of the enzyme, Rpb5, Rpb6, and Rpb8 bind to Rpb1, and Rpb9 binds to both Rpb1 and Rpb2. The Rpb4/7 complex binds to the Pol II core via subunit Rpb7 and protrudes from the Pol II core surface near subunit Rpb6.

Structural Elements

The Rpb1 side of the Pol II cleft is formed by a mobile clamp, whereas the Rpb2 side consists of the lobe and protrusion domains. The entrance to the cleft is formed between the upper and the lower jaw, which include subunits Rpb9 and Rpb5, respectively. The end of the cleft is blocked by a protein wall. The active center is at the floor of the cleft, between the protrusion, the wall, and the clamp. Before the active center and opposite of the wall, a long bridge helix spans the cleft. The bridge partially lines a pore in the active center, which widens toward the other side of the enzyme, creating an inverted funnel. The rim of the pore includes the highly conserved aspartate loop of Rpb1 that binds a catalytic Mg^{2+} ion, termed metal A. A second metal ion, metal B, is weakly bound next to metal A further in the pore. Both metal ions are accessible from one side.

The clamp is trapped in two different open states in the free core structures, but is rotated and closed in the structure of the Pol II transcription elongation complex (EC) that comprises template DNA and the RNA transcript. In this structure, the clamp binds the DNA template strand with three out of five switch regions. The switch regions form the base of the clamp, connecting to the remainder of Pol II. Upon clamp closure,

the switches change conformation or undergo folding transitions. The closed conformation of the clamp is also observed in the complete Pol II that contains the Rpb4/7 complex. The Rpb4/7 complex appears to form a wedge between the clamp and subunit Rpb6, thus preventing clamp opening.

The Rpb1 polypeptide chain protrudes below the Rpb4/7 complex on the outside of Pol II, and gets disordered after a few residues. These residues of Rpb1 constitute the beginning of a flexible linker that connects to the mobile C-terminal repeat domain (CTD). The CTD, a unique feature of Pol II, consists of repeats of a heptapeptide with the consensus sequence Tyr–Ser–Pro–Thr–Ser–Pro–Ser. A total of 26 and 52 CTD repeats is found in yeast and human Rpb1, respectively.

Mechanism

Transcription Cycle

The transcription cycle is divided into three phases: initiation, elongation, and termination. Steps during initiation include promoter binding, DNA melting, and synthesis of short RNA transcripts. The transition from initiation to elongation is referred to as promoter escape, and results in a stable EC that is characterized by an open DNA region, the transcription bubble. The bubble contains the DNA–RNA hybrid, a heteroduplex of 8–9 base pairs (bp). The growing RNA 3'-end is located at the end of the hybrid that is engaged with the Pol II active site. Pol II alone can maintain an open transcription bubble, translocate along the DNA template, synthesize RNA, and detect errors in the nascent RNA. For all other steps, however, Pol II requires the help of additional proteins.

Several steps of the transcription cycle are accompanied by phosphorylation or dephosphorylation of the Pol II CTD. During initiation, the CTD becomes phosphorylated, and the CTD phosphorylation pattern changes during elongation. CTD phosphorylation patterns govern specific interaction with RNA processing factors, thereby coupling transcription to RNA processing. The CTD is flexibly linked to a region beyond the saddle, from which RNA exits, consistent with its role in coupling transcription to messenger RNA (mRNA) processing. Several kinases and at least one phosphatase control the phosphorylation state of the Pol II CTD.

^aCore, sequence partially homologous in all RNA polymerases; common, shared by all eukaryotic RNA polymerases; and Rpb4/7, Rpb4/7 heterodimer and its structural counterparts.

Initiation

Transcription initiation begins with formation of the pre-initiation complex (PIC) on promoter DNA. The PIC contains Pol II and the general transcription factors TFIIB, -D, -E, -F, and -H. The general factors are involved in sequence-specific promoter recognition (TFIIB and TFIID), prevention of nonspecific DNA binding (TFIIF), and DNA melting and CTD phosphorylation (TFIIE and TFIIH). Recently, the structure of RNA Pol II in complex with TFIIB was presented. The structure shows that to initiate gene transcription, promoter DNA is positioned over the Pol II active center cleft with the B-core domain that binds the wall at the end of the cleft. DNA is then opened with the help of the B-linker that binds the Pol II rudder and clamp coiled coil at the edge of the cleft. The DNA template strand slips into the cleft and is scanned for the transcription start site with the help of the B-reader that approaches the active site. RNA synthesis initiates within the bubble. The early transcribing complex is functionally unstable. Short RNAs are frequently released and Pol II has to restart transcription (abortive cycling).

Synthesis of the RNA chain and rewinding of upstream DNA displace the B-reader and B-linker, respectively, to trigger TFIIB release and EC formation. The elongating RNA extends over the dock domain, preventing reassociation of the TFIIB ribbon with Pol II during elongation.

Elongation

During elongation, downstream DNA enters Pol II at two mobile jaws, and extends through the cleft toward the active site. Beyond the active site, a 9-bp DNA–RNA hybrid extends upward, toward the wall. The axes of the downstream DNA duplex and the DNA–RNA hybrid heteroduplex enclose an angle of almost 90°. The growing RNA 3'-end is located above the pore, which allows entry of nucleoside triphosphate

Figure 1 RNA polymerase II structures. (a) Ribbon model of the complete yeast RNA polymerase II crystal structure. The 12 subunits are shown in different colors. (b) Ribbon model of the RNA polymerase II EC. The DNA template and nontemplate strands are in blue and cyan, respectively, and the RNA is in red. Metal ion A is depicted as a magenta sphere. Zinc ions are shown as cyan spheres.

(NTP) substrates from below. In the crystal structure of the Pol II EC, the incoming DNA duplex is mobile but is bound for strand separation closer to the active site. Downstream DNA runs along the Rpb1 face of the cleft. Upstream of the point of DNA-strand separation, the DNA template strand positions a base in the active site that directs RNA synthesis.

The property of the polymerase to stay attached to the template, even during transcription of long genes, is often referred to as 'processivity'. The major cause of processivity is the high stability of the Pol II EC, caused by tight binding of the DNA–RNA hybrid. This stability can be accounted for by the highly complementary hybrid-binding site on Pol II, which is partially created upon clamp closure and folding of the switches. Several Pol II structural elements maintain the hybrid and the transcription bubble during elongation, including the

fork loops, the top of the wall, and three loops protruding from the edge of the clamp, called 'rudder', 'lid', and 'zipper'.

Extension of the RNA chain is achieved during the nucleotide addition cycle (NAC). The NAC begins with binding of an NTP substrate to the transcription EC. Catalytic addition of the nucleotide to the growing 3'-end of the RNA leads to the formation of a pyrophosphate ion. Pyrophosphate release leads to the pre-translocation state, in which the newly added, 3'-terminal RNA nucleotide remains in the substrate site. Finally, translocation of DNA and RNA results in the post-translocation state, in which the substrate site is free for binding the next NTP, and the NAC can be repeated. Recent structural studies of ECs of the eukaryotic Pol II and the bacterial RNA polymerase have revealed different functional states that reflect intermediates in the NAC.

Specificity for synthesizing RNA rather than DNA is achieved by at least three mechanisms. First, the discriminating 2'-OH group of the incoming NTP may be hydrogen-bonded by a conserved Pol II residue. Second, 2'-OH groups of the last few nucleotides that were incorporated into the growing RNA are directly hydrogen-bonded by Pol II residues. Finally, the active center of Pol II is complementary to the resulting DNA–RNA hybrid duplex that adopts a conformation intermediary between canonical A and B forms.

It is a mystery of the transcription mechanism how rapid translocation of nucleic acids can be achieved while nucleic acids are bound tightly by Pol II. Hints for understanding translocation are however provided by the Pol II structures. First, nucleic acids are only contacted via their backbones; base interactions that would impede translocation are not observed. Second, long-range electrostatic attraction of the nucleic acid backbones by positively charged protein groups in a second shell may enable tight binding of nucleic acids without restricting their movement. Finally, translocation is accompanied by conformational changes in Pol II that maintain some of the protein–nucleic acid contacts during translocation. Structural analysis of Pol II ECs in pre-translocation, post-translocation, and in an intermediate state show that such conformational changes include folding of the trigger loop and bending of the bridge helix.

Pol II elongation is inhibited by the cyclic octapeptide α -amanitin, the toxin of the death cap mushroom. α -Amanitin does not greatly influence NTP binding, and a phosphodiester bond can still be formed when the toxin is added to an EC. However, the rate of transcription is dramatically reduced. Only a handful of nucleotides is incorporated per minute. In the structure of an α -amanitin containing Pol II EC, α -amanitin binds to the trigger loop and to the bridge helix. The structure suggests that α -amanitin inhibits Pol II by trapping the trigger loop and shifted bridge helix, thereby stabilizing a conformation of the EC that represents a translocation intermediate.

Pol II does not move along the DNA template in a unidirectional manner; rather, it oscillates between movements forward and backward (backtracking). During backtracking, RNA is extruded through the Pol II pore into the funnel. Backtracking can lead to transcriptional pausing and arrest. Pausing is defined as a temporary block to elongation, from which Pol II can escape by itself. By contrast, Pol II cannot escape from arrest without the help of the transcript cleavage factor TFIIS,

which stimulates a weak intrinsic nuclease activity of Pol II, which cleaves RNA. Access of TFIIS to the Pol II active site is apparently provided via the funnel and pore. Backtracking and TFIIS action may also underlie proofreading of the nascent transcript. During proofreading, a misincorporated nucleotide results in a mismatch base pair within the DNA–RNA hybrid. The induced distortion of the hybrid destabilizes the EC and can lead to immediate cleavage of a mononucleotide, or it can trigger in backtracking, which results in threading of a short stretch of RNA (comprising the misincorporated nucleotide) into the pore and cleavage with the help of TFIIS. Any proofreading reaction creates a new RNA 3'-end at the active site, from which transcription can resume.

Termination

Transcription termination occurs in a reaction coupled to RNA 3'-end processing. Most eukaryotic mRNA precursors are cleaved in a site-specific manner in the 3'-untranslated region, followed by polyadenylation of the upstream cleavage product. A large number of proteins are involved in these reactions. The exact mechanism of coupling between 3'-end processing and transcription termination remains unclear. Termination is accompanied by dephosphorylation of the Pol II CTD, but the precise timing of Pol II dephosphorylation is also unclear. Dephosphorylation is required for the reinitiation of transcription, because Pol II can only join an initiation complex in its unphosphorylated form. The CTD phosphatase Fcp1 plays a key role in Pol II dephosphorylation and recycling. Fcp1 binds to Pol II via Rpb4. Rpb4 apparently recruits Fcp1 to the vicinity of the CTD, because the Rpb4/7 complex binds near the linker that connects the Pol II core to the CTD.

Conservation

Pol II belongs to the family of cellular RNA polymerases, which also includes two other eukaryotic RNA polymerases, Pol I and Pol III, and the bacterial and archaeal RNA polymerases. All three eukaryotic RNA polymerases share five common subunits (Table 1). Four core subunits of Pol II, Rpb1, Rpb2, Rpb3, and Rpb11, as well as subunit Rpb9, all have close homologs in Pol I and Pol III. The Rpb4/7 complex of Pol II also has structural and functional counterparts in Pol I and Pol III, and in the archaeal RNA polymerase. As the 12 subunits of Pol II are either identical or homologous in all three eukaryotic enzymes, the Pol II structure is a good model for all eukaryotic RNA polymerases. Comparison of Pol II with a bacterial RNA polymerase structure revealed that five core subunits underlie a general RNA polymerase architecture with an active center cleft. Twenty-two regions of sequence homology cluster around the active site and generally adopt the same structure in all cellular RNA polymerases. The structurally conserved core includes the functional elements of the active center, indicating that all cellular RNA polymerases share common mechanistic features. Homologs for all Pol II subunits (except Rpb8) are found in archaeal RNA polymerases. Thus, the overall structure of archaeal RNA polymerases is very similar to that of Pol II except for several external domains.

The Pol II structure is strikingly different from structures of the many single subunit DNA and RNA polymerases. However,

in functional complexes of these diverse enzymes, nucleic acids take a similar course through the active center. The entering DNA duplex encloses an angle of almost 90° with the exiting template–product duplex. At the location of the bend, subsequent DNA template bases are twisted. This twist aligns the coding base with the binding site for the incoming NTP substrate. The NTP enters through an opening that is found in all polymerases, and generally binds between an α -helix and two catalytic metal ions. The exiting template–product duplex is bound from the minor groove side in all polymerases. Conformational changes upon nucleic acid binding have been detected for several different polymerases, but the nature of this induced fit differs.

Glossary

cDNA DNA that has been created from RNA using reverse transcription.

Microarray A device typically used for monitoring gene expression for a large number of genes. They consist of an ordered array of different elements (usually nucleic acids complementary to the genes of interest) that are usually printed or synthesized *in situ* on a solid surface. Microscopic beads can also be used.

Probe The individual elements bound to a microarray consisting of long oligonucleotides, short oligonucleotides (25mers), fragments of genomic DNA or cDNAs.

Read The sequence of bases determined from a single segment of sample nucleic acid by a sequencing instrument.

Read length The number of individual bases identified in a continuous read.

RNA Ribonucleic acid. Single-stranded molecules transcribed from DNA.

RNA-seq Whole transcriptome analysis based on high-throughput sequencing technologies.

Second-generation sequencing (SGS) High-throughput sequencing based on short polymerase chain reaction (PCR) amplified DNA fragments, usually based on wash-and-scan techniques.

Serial analysis of gene expression (SAGE) A method used in the genome-wide monitoring of gene expression in which short sequence tags from different cDNAs are isolated, sequenced, and counted.

Third-generation sequencing (TGS) High-throughput direct sequencing of single molecules of nucleic acid without the need of amplification or halting between read steps.

Gene Expression Data for Discovery and Classification

Gene expression is the process by which gene sequences are transcribed into functional gene products such as proteins or functional RNAs (e.g., rRNA, tRNA, small RNA). The process of gene expression is used by all known organisms and can be regulated and modulated at several levels (transcription initiation, splicing, alternative splicing, mRNA stability, post-transcriptional regulation, and eventually translational and posttranslational regulation mechanisms). Gene expression and regulation are the basis of cell development and differentiation. They also allow the cell to adapt to different conditions. By controlling the time, location, and expression level, gene transcripts can have a profound effect on the functions of genes within cells or in multicellular organisms. Genome-wide analysis of gene expression allows for the detection and the quantification of transcript levels for every known gene in the genome of the cell type and organism of interest. The primary use for whole-genome expression analysis is the identification of cell or tissue phenotypes as well as the discovery of novel genes or pathways involved in particular molecular processes and disease development. For example, genome-wide analysis of gene expression can be used to distinguish two different biological states, such as, acute myoblastic leukemia and acute lymphoblastic leukemia, which are relatively difficult to distinguish from one another using conventional molecular and cytological approaches. New genes or pathways induced or repressed in the condition of interest, relative to the reference condition, may provide a better description of the biological processes under study, present new molecular reporters and novel drug targets, predict patient's disease classifications, and also optimize treatments. To analyze gene expression in a genome-wide manner, total RNA is collected from the condition of interest

and from a control condition and analyzed by different genome-wide methodologies (e.g., microarray or sequencing technologies – see described methods below). Newly developed software are then used to examine these large genome-wide expression data projects.

Expressed Sequence Tag

In 1991, the primary tool employed for human gene discovery was a method using expressed sequence tags (ESTs). ESTs are single-pass sequence reads derived from complementary DNA (cDNA). ESTs are typically around 100–800 base pairs (bp) in length, unedited, and randomly selected. Because the ESTs are sequenced only once, the reads are susceptible to errors. Often times, the quality of the base reads for each EST was poor at the beginning of the sequence, improved significantly in the middle, and then diminished again at the end. Phred scores provided a measure of sequence quality of ESTs and were used to extract sequences of a minimal specified quality. Today, EST is no longer widely used because of its inherent drawbacks, which are low-throughput capabilities, redundancy, under-representation, and over-representation.

Serial Analysis of Gene Expression

Serial analysis of gene expression (SAGE) was developed in 1995 by Dr. Victor Velculescu and provides a snapshot of transcript population within a sample by analyzing small tags that correspond to the 3' fragments of messenger RNA (mRNA) (Figure 1). First, cDNA is synthesized from mRNA using biotinylated oligo(dT) primer and then is cleaved with a

Figure 1 Serial analysis of gene expression (SAGE). RNA is extracted and purified from desired samples. mRNA is converted into double-stranded cDNA by reverse transcriptase with biotinylated poly-T tails as primers. The biotinylated cDNA is fragmented with anchoring enzymes that recognize and cut at their respective restriction sites that are usually found naturally in every few hundred basepairs. The biotinylated ends of the fragmented cDNA are bound to streptavidin beads and split into two portions. Appropriate adaptors with an endonuclease site for tagging enzymes are ligated to each cDNA fragment at the cleaved end. Tagging enzymes are added to cleave a small distance from their endonuclease sites found at each adaptor, releasing the fragmented cDNA (up to 26 bp) from the beads. Blunt ends from each of the two portions of fragmented cDNA are ligated together, forming a ditag, and then amplified by PCR. After PCR, ditags are cleaved at their adaptors, concatenated, and then cloned into plasmids. Once cloned, plasmids are then sequenced, mapped back to the gene and subsequently analyzed for gene expression.

restriction enzyme (anchoring enzyme) that is expected to cut each transcript at least once. The most 3' fragment of the cleaved cDNA is bound to streptavidin beads at its poly(A) tail that is complemented by biotinylated thymidines. Bound cDNA fragments are then ligated at the anchoring cleavage site with linkers that contain a type IIS restriction site. Type IIS endonucleases (tagging enzymes) cleave at a specific distance up to 20 bp away from the recognition site. This process is designed so that cleavage with the tagging enzymes results in the release of the linker along with a short piece of cDNA (tag) of around 9 bp. Released tags are then ligated together at their blunt ends to form a ditag, which serves as a template for polymerase chain reaction (PCR) amplification using primers specific to the linkers. Following PCR amplification, the flanking linkers are cleaved from the ditags using the anchoring enzyme. Cleaved ditags are subsequently concatenated, cloned into a plasmid vector, and then sequenced.

With SAGE, up to 20 000 tags can be sequenced in a single experiment. With full-genome sequence information, the sequenced SAGE tags can be mapped back to the gene. This approach provides for a highly quantitative analysis since the number of tags for a particular gene can be counted. Since the advent of SAGE, several more robust variants, LongSAGE, RL-SAGE, and SuperSAGE, have been developed. These newer variants allow up to 100 000 sequenced tags per trial, thus providing a more comprehensive profile of the transcriptome, and capture longer tags, up to 26 bp, enabling more confident identification of the source gene. Though there have been improvements, SAGE is no longer widely implemented because it is highly labor intensive and is relatively low throughput compared to the newly developed sequencing technologies described below.

DNA Microarray

DNA microarrays consist of an arrayed series of thousands of microscopic spots of DNA oligonucleotides, each containing specific DNA sequences, called 'probes' or 'reporters'. Genes or DNA fragments of interest are amplified with PCR, cleaned up, and printed as a two-dimensional (2D) array using robotic microarraying devices that are able to dispense small quantities of solution at a precise location on a solid support, typically a glass slide due to its low inherent fluorescence. These glass slides are usually coated with hydrophobic poly-lysine or aminosilanes, which limit the spread of DNA on the slides. Other microarray platforms, such as Illumina, use microscopic beads instead of a solid support.

Alternatively, solid-phase *in situ* synthesis of DNA probes from genes of interest can also be implemented in constructing a microarray using a combination of light-directed oligonucleotide chemistry and photolithography. This technology was first developed by Affymetrix but is now available from various other companies such as Agilent. Nucleic acid arrays manufactured from this method allows for high information content with up to 1 000 000 oligonucleotides selected from sequencing databases and precisely synthesized on a small platform (Figure 2). Since these arrays are designed *in silico*, intermediates such as cDNA libraries, PCR, and clones are unnecessary

Figure 2 Microarray. Nucleic acid microarrays must first be produced by either *in situ* synthesis or by robotic deposition of nucleic acids. For *in situ* synthesis, multiple probes per gene are placed on the array, while in the case of robotic deposition longer (up to 1000 bp) double-stranded DNA probe(s) is used for each gene. RNA from various samples is extracted and purified. The RNA can be converted into cDNA by reverse transcriptase in order to produce labeled cRNA by *in vitro* transcription (IVT) or have the cDNA labeled with a tag such as biotin or fluorescent dye. In addition, RNA can also be directly labeled. Labeled RNA/cDNA/cRNA are then hybridized to the arrays. After washing, and appropriate secondary fluorescent dyes (if necessary) are added, the intensities of light from the hybridized dyes are detected and recorded. Clustergrams and relative expression levels for each gene are extrapolated by comparing microarray data between various conditions.

and thus the risk of mislabeling is reduced. In addition, this method provides more control over the sample amount deposited onto each location on the array. In order to gain confidence, different multiple probes are synthesized for a given gene.

Transcripts from the sample of interest are converted into cDNA or cRNA (target) and typically labeled with fluorophores or biotin, but chemiluminescent molecules or radioactive isotopes can also be used. Labeled cDNA or cRNA is then hybridized to the DNA microarray under high-stringency conditions. The underlying principle of gene expression level analysis using DNA microarrays is that the transcript level for a particular gene will directly correspond to the amount of hybridization detected on the probe representing that same gene. Probe-target hybridization is detected and quantified using various methods depending on the application. Usually, the background-subtracted hybridization levels from probes representing the same gene are averaged because different oligonucleotide probes have distinct hybridization properties. This approach allows for uses such as distinguishing genes that are highly expressed from those that are lowly expressed.

Tiling arrays are a subtype of microarrays that use short probes that cover the entire length of the genome. Depending on the probe length and spacing, different resolutions can be achieved. The advantage of tiling arrays over traditional microarrays is that the detection of unidentified genes, alternative splice sites, single-feature polymorphisms, and transcript variants are made possible.

Microarray Analysis

High-throughput techniques such as DNA microarrays can produce a large amount of raw data. With proper analytical

approaches, a significant amount of biological information can be extrapolated from microarray data. Clustering is a method of analysis that organizes data and groups genes according to their similarity in gene expression patterns. Since genes with similar biological roles will often have similar patterns of expression, genes involved in related processes are often clustered together. Pairwise average-linkage cluster analysis is a widely used tool that creates hierarchical clusters. Relationships between genes are represented by trees, branch lengths of which reflect the degree of similarity between genes.

Another technique for analyzing microarray data is the ontology method that implements the guilt-by-association approach by inferring possible functions to genes by using prior biological knowledge of other co-expressed genes. Often times, known inhibitors of a biological pathway can be used to elicit the up- or downregulation of clusters of genes, and thus uncharacterized genes can be investigated by their association with other previously known genes that they are co-regulated with. Gene expression analysis by microarray is still being implemented today and is still contributing significantly to our understanding of gene expression and transcript profiles. However, with the advent of newer, cheaper, and more powerful tools such as next-generation sequencing technologies, microarray technology may be phased out in the near future.

Next-Generation Sequencing Technologies

In 1977, Sanger sequencing became available and, since then, has undergone numerous improvements that allowed for automation. Up until recent years, large sequencing projects (e.g., whole genome sequencing of species) have depended on Sanger sequencing. However, in the past decade or so, there

Figure 3 RNA-Seq with second-generation and third-generation sequencing technology. Whole RNA extracts are purified and converted into cDNA. For RNA-Seq using second-generation sequencing (SGS) technology, cDNA is sheared into fragments and have appropriate adaptors added. cDNA fragments are added to either DNA capture beads or flowcells and then PCR amplified creating colonies. Using a series of wash-and-scan cycles, fluorescently labeled nucleotides are incorporated or ligated according to the sequence of the template strand. Highly sensitive cameras are able to detect and record which nucleotide was incorporated by the light signal emitted. Sequence reads are then mapped to the genome for analysis. For RNA-seq using third-generation sequencing (TGS) (only Pacific Biosciences technology is shown here), whole cDNA strands are individually placed into nanowells, and are replicated with fluorescently labeled nucleotides by DNA polymerases. A different color light signal is emitted for each type of nucleotide as they are incorporated into the replicated strand. The series of light signals is detected and recorded by cameras, and then converted into sequence reads, which are then mapped back to genes for analysis.

have been several newly developed sequencing methods, collectively called next-generation sequencing (NGS) (Figure 3), that have both transformed the field of whole genome sequencing and also opened up new applications for sequencing-based approaches such as transcriptome analysis.

In 2005, second-generation sequencing technology (SGS) had become commercially available. Unlike Sanger sequencing, cloning the DNA template into bacterial vectors is unnecessary. On top of saving time and labor, the advantage of bypassing the need for bacterial cloning is that cloning biases, such as cloning difficulties of AT-rich regions and genes that are toxic to bacteria, are circumvented. In addition, SGS provides for a much higher throughput than automated Sanger methods by achieving a tremendous degree of parallelization where up to billions of sequencing reactions within small volumes are taking place at the same time. In most SGS methods, template DNA is sheared into fragments, bound to adaptors, and PCR amplified in order to generate clonal representations of the original template DNA. Tens of thousands of identical PCR-amplified fragments

are usually spatially immobilized on beads or on a given location on an array making up a PCR colony (polony) or clusters. These clusters are read by numerous cycles of washing and scanning operations where sequencing is accomplished by employing various enzymes (e.g., ligases and polymerases) and reagents (e.g., fluorescently labeled nucleotides) to produce a series of fluorescent signals representing the average sequence of an individual cluster. The number of cycles of wash-and-scan determines the length of each read and is usually limited by the amount of noise produced by the incorporation of out-of-phase nucleotides as the read becomes longer. Because of the numerous scan-and-wash cycles, the length of time required to complete a run usually lasts for several days. The massive parallel series of light signals are recorded by highly sensitive detection systems and subsequently decoded to determine the base sequence of the DNA. During the decoding process, also known as 'base calling', each called base is generally given a quality score. Timely analysis and reconstruction of the large amount of sequenced reads are made possible by significant

advancements in computational power and data storage, along with a number of software tools that are available.

Roches' 454 genome sequencer was the first commercially available SGS. Its average read length is around 400–500 bp, which is the longest among the SGS systems available today. It is able to produce 400–600 million bases per run or about 1 billion bases per day. The 454 sequencing method starts with the generation of a library containing single-stranded template DNA with attached adaptors. This library is then immobilized onto DNA capture beads with only one single-stranded DNA fragment per bead. By emulsion PCR, the DNA library is amplified on each bead and then placed into individual wells on a PicoTiterPlate. With the supplementation of sequencing enzymes and materials, the addition of nucleotides complementary to the template DNA results in a base-by-base chemiluminescent light that is detected and recorded by the 454 genome sequencer.

Applied Biosystems' SOLiD system is another SGS system that has a shorter read length of 35–50 bp but is able to generate a high throughput of about 100 gigabases per run (or 8 gigabases per day). Like the 454 genome sequencer, the SOLiD system uses beads to immobilize and PCR-amplify template strands. Once the template strands are amplified and denatured, their 3' ends are modified to allow for covalent bonding to a glass slide. The 3' modified beads are then deposited onto glass slides which allow for high densities of beads per slide and thus a high level of throughput. Primers are hybridized to adaptors at the ends of each template strand, and a set of four fluorescently labeled di-probes is allowed to compete for the primers by interrogating every first and second base of each ligation cycle. Multiple rounds of ligation, detection, and cleavage are the driving mechanism for this sequencing-by-ligation approach. After the first series of ligation cycles, the extension product is removed and the template is reset with the hybridization of primers that are offset by one nucleotide from the previous primer and a subsequent series of ligation reactions takes place. This process is repeated with a total of five primer resets for each sequence tag. For each template fragment, the multiple series of fluorescence produced by the ligation cycles are detected, recorded, and threaded together in order to generate a complete read.

Illumina's (formally known as Solexa) sequencers, such as the Genome Analyser and HiSeq 2000, are capable of producing high-throughput sequencing, up to 200 gigabases per run (or up to 25 gigabases a day) with a read length of 35–150 bp. Template strands are first fragmented and ligated with adaptors. Then the template fragments are hybridized to a flat, optically transparent surface, where they are bridge-amplified to create a highly dense sequencing flowcell containing tens of millions of clusters each containing around 1000 copies of the same template fragment. Illumina implements a sequencing-by-synthesis approach by using reversible terminators with removable four-color fluorescent dyes to generate a base-by-base sequence. Each type of nucleotide is distinguished by a different color. Fluorescence detection is accomplished with laser excitation and total internal reflection optics.

The Polonator is an NGS that is based upon sequencing-by-ligation that has an open-source platform where users can use off-the-shelf reagents and freely download protocols and software. The open-source approach allows for users to modify protocols, reagents, and software to custom-fit their sequencing

application. However, the Polonator has the shortest read lengths when compared to other NGS systems.

In addition to genome sequencing, NGS systems are applied to sequence cDNA derived from the whole transcriptomes of an organism in order to analyze expression profiles, transcript boundaries, intron/exon junctions, alternative expression, and also discover novel transcripts in a high-throughput manner. The obtainment of transcriptomics data by NGS is collectively known as deep RNA sequencing or RNA-seq. In 2008, the implementation of RNA-seq was first reported in yeast, and then was quickly adopted for use of transcriptome analysis in several other organisms. The advantages of RNA-seq over previous analytical sequencing tools such as EST and SAGE are that RNA-seq has a much higher throughput and increased sequencing depth, which leads to better resolution of expression profiles. Though microarray has a genome-wide coverage, nucleic acid arrays are not available for all organisms, while RNA-seq can be used on any organism. In addition, microarray expression data can be biased by the binding affinities of each individual probe. Another advantage is that RNA-seq is able to identify transcript boundaries and intron/exon junctions at a single-nucleotide resolution.

Third-Generation Sequencing

More recently, a few new companies, such as Helicos Biosciences and Pacific Biosciences, are developing advanced sequencing methods that do not require template amplification but rather directly sequence from single template molecules. These systems are commonly referred to as third-generation sequencing (TGS) platforms (Figure 3). The advantage of directly sequencing from single template molecules is that clonal duplication and amplification biases due to difficulties in amplifying certain regions of template strands are avoided. Also, the amplification process can introduce errors in the replicated template strands.

In the Helicos system, DNA or cDNA is sheared and turned into single-stranded molecules. Fluorescently labeled poly-A adaptors are added to the ends of the sheared strands and then hybridized to poly-T oligonucleotide capture-strands bound to a flowcell. A highly sensitive camera that is able to detect single-molecule fluorescence captures the locations of each of the billions of hybridized template strands. After the fluorescent label is removed from the adaptors, a series of wash-and-scan cycles is initiated; a single type of fluorescently labeled nucleotides and polymerases are washed over the flowcell, followed by fluorescence detection by imaging and removal of the fluorescent group. The wash-and-scan cycle is then repeated with the other three nucleotides. Multiple four-base cycles result in reads of around 25 bp.

Pacific Biosciences has developed a real-time single-molecule sequencing system, PacBio RS (Figure 3), that is capable of 30 minute sequencing runs because it does not require the conventional wash-and-scan method, which can normally take up to several days. A thin 100-nm-thick metal film is perforated with an array of nanoscopic holes and bound to a glass substrate, creating wells that are tens of nanometers in diameter. A laser light is shined through the glass substrate, illuminating only the bottom 30 nm of each well. Each well

typically has a single DNA polymerase anchored to the glass bottom and is small enough to allow for only one template strand. Fluorescently labeled nucleotides that have different fluorescent colors depending on the nucleotide are washed over the nanoscopic wells and are incorporated into the sequencing strand by the DNA polymerase. These nucleotides have fluorescent dyes attached to the phosphate chain instead of the base, thus preventing the inactivation of the DNA polymerase. As the fluorescently labeled nucleotides are incorporated one-by-one via the DNA polymerase, the fluorescent dye is excited by the laser, transmits a color signal that lasts milliseconds, and then is cleaved off by the DNA polymerase to allow for additional rounds of nucleotide incorporation and fluorescence. The series of color fluorescence is detected and decoded to produce reads of over 1000 bp.

Analytical Tools for NGS Expression Data

The high throughput and deepness of quantitative measurements produced by NGS technology comes at the price of examining millions to billions of reads. Though the first users have created their own computer programs to study the numerous reads, a new breed of sophisticated algorithms and software tools has emerged to help analyze the massive data sets produced by RNA-seq. These analytical tools are used for transcript discovery, RNA quantification and mapping, and also identification of transcript variants and splice sites.

With a given gene model, the total number of mapped reads can be tallied for a particular gene as a measure of gene expression. The number of reads is naturally a function of the molar concentration of mRNA but must be normalized according to the length of each mRNA. A common approach is to normalize the read count by the length of the transcript and the number of millions of mappable reads to obtain reads per kilobase per million (RPKM) values. Within a given sample, RPKM values for genes are directly comparable to give relative expression values. However, RPKM values vary depending on the software package employed and can also be influenced by experimental factors such as quality of input RNA, the amount of ribosomal RNA remaining in the sample, size selection procedures, and the accuracy of the gene model used. Amplification biases can also obstruct uniform sequence coverage across the transcriptome, though TGS technologies circumvent this problem by bypassing the amplification process altogether.

In addition to quantifying gene expression, RNA-seq allows for the investigation of the correspondence between gene and

transcript model. With alternative splicing, alternative promoter employment, and differing 3' poly (A) tail sites, various types of transcripts can be derived by a single gene. RNA-seq is capable of using reads that map across splice junctions to identify splice sites and also discover alternatively spliced transcript isoforms. Using more advanced software, users are capable of extracting more information from their RNA-seq data, such as analysis of transcript modeling, quantifying specific isoforms, and investigating sequence variance due to single-nucleotide polymorphisms, private mutation, or RNA editing. Bioinformatic tools are constantly being developed in order to match the quickly evolving sequencing technology.

Though current analytical tools of investigating transcripts on a genome-wide level have their own distinct challenges, they offer more advantages than previous methods such as higher-throughput, wider-coverage, and increased sensitivity. Today, with RNA-seq technology, we are able to quantify differences in gene expression at a single-nucleotide resolution across multiple samples and conditions. Though we still have much to learn and discover, we draw closer to understanding how genomes are capable of encoding diverse patterns of gene expression that define each cell type/stage and also elicit a distinct response from various stimuli/conditions.

Glossary

Ariboflavinosis A deficiency of riboflavin in the diet.

Crista (pl. cristae) Any of numerous infoldings of the inner mitochondrial membrane in eukaryotic cells.

Nebenkern A globular structure in a spermatid that results from interlocking and fusion of the mitochondria during spermatogenesis.

Megamitochondrial Structure

Under some conditions, the megamitochondria are virtual simulacra of their normal size counterparts; that is, on a unit mitochondrial area basis they display the same number and arrangement of cristae as do normal mitochondria (Figure 1), although in some cases they may contain within their matrix a small stack of closely packed, short cristae. In other conditions, the megamitochondria have very short cristae that protrude inward from the boundary membrane in a manner not unlike a picket fence. In still others, the cristae are very rare, with the megamitochondria consisting of a morphologically conventional outer membrane and a smooth inner boundary membrane that is almost devoid of cristae. In all types of megamitochondria, the inner compartment contains moderately dense, homogeneous material. In some cases of human

thyroid tumors, the matrix compartment contains a jumble of dense ribbons of undefinable length. In certain types of giant mitochondria, an expanded crista contains a bundle of helical filaments. Filaments of this type occurring in normal hepatic mitochondria consist of three distinct, but otherwise uncharacterized, proteins.

It is well established that normal mitochondria replicate by division, but the morphological pathway by which this process is accomplished was unclear. The megamitochondrial model has been used successfully to settle this point. Based on restoration to normal size of experimentally induced megamitochondria, there appear to be two distinct pathways in mitochondrial division; during recovery, only one of the two mechanisms is called upon, depending on the agent that evoked the

Figure 1 Transmission electron micrograph of a hepatic megamitochondrion induced in a mouse by riboflavin deficiency. Note the typical distribution of cristae and the presence of dense matrix granules. The diameter of this organelle is approximately 6 times as large as that of normal hepatic mitochondria. At the left, the large mitochondrion is linked to two smaller organelles by means of small myelin figures, indicating that it is still in the process of enlargement. Original magnification, $\times 9000$.

Figure 2 Transmission electron micrograph of a dividing hepatic megamitochondrion during recovery from ariboflavinosis. A small bud is subtended by a membranous partition; ingrowth of the outer membrane ultimately leads to the separation of the bud, which is equal in size to a typical mitochondrion, from the enlarged organelle. Repetition of this process results in mitochondrial normalization in terms of size. Original magnification, $\times 34\,000$.

megamitochondria in the first place. The first mechanism involves the formation of a membranous partition, probably of boundary membrane origin, that spans the organelle, frequently at the base of a bud (Figure 2). This is followed by ingrowth of the outer membrane into the partition. Like a closing iris diaphragm, the outer membrane eventually completes its incursion, and two daughter mitochondria result. Repetition of this process ultimately leads to the disappearance of megamitochondria and to the appearance of organelles of normal size. The second pathway involves a simple elongation and attenuation of the equator of the megamitochondrion until membranes from opposite sides of the organelle touch and fuse. In effect, the giant mitochondrion has been pulled apart. The progeny of such division repeatedly undergoes the same process to finally restore the mitochondria to their accustomed dimensions. What controls the selection of a particular pathway for mitochondrial division is completely unknown.

Gi Family of Heterotrimeric G Proteins

M E Linder, Cornell University, Ithaca, NY, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Chemokine Small, secreted proteins that guide the migration of white blood cells.

Effector A protein whose activity is changed in response to a stimulus.

Hormone A circulating peptide or chemical that acts on target organs at a distance from its site of synthesis.

Neurotransmitter A chemical messenger released by a nerve cell at a synapse.

Receptor A protein at the cell surface or in the cytoplasm that binds a specific small molecule or protein and activates other proteins to produce a cellular response.

Second messenger A small molecule synthesized intracellularly in response to an extracellular stimulus that propagates the signal by binding to an effector and modulating its activity.

Overview of the Gi Family

G_i was discovered in the early 1980s as the G protein that mediates hormonal inhibition of cyclic adenosine monophosphate (cAMP) production. Its discovery followed that of G_s, the G protein that stimulates cAMP production and G_t, the G protein that regulates cyclic guanosine monophosphate (cGMP) levels in the retina. Characterization of G_s, G_i, and G_t revealed a structurally homologous family of guanine-nucleotide-binding proteins that are heterotrimers with subunits designated α , β , and γ . The α subunit contains the guanine-nucleotide-binding site. G protein α subunits act as molecular switches between an active and inactive state depending on whether GDP or GTP is bound. GTP-bound α is the active form and regulates downstream targets. The GDP-bound form of the α subunit is the inactive state.

In mammals, there are 16 different genes that encode G protein α subunits that range in size from 39 to 45 kDa. G _{α} proteins encoded by these genes can be divided into four families based on function and primary amino acid sequence homology. These are G_s, G_i, G_q, and G_{12/13}. The G_i family is the most functionally diverse of the G-protein families. It can be subdivided into five groups – G_{i1}, G_o, G_{i2}, G₁₂, and G₁₃ – according to the identity of the α subunit. The evolutionary relationship among the G_i family α subunits is shown in Figure 1. G _{α} subunits associate with G _{$\beta\gamma$} dimers composed of combinations of the five G _{β} and 12 G _{γ} subunits. Although not all combinations are possible, a large number of heterotrimers can be generated within this family. Like all heterotrimeric G proteins, G_i family members undergo a cycle of nucleotide exchange and hydrolysis when activated by receptors (Figure 2). Binding of GTP to G _{α} induces dissociation from G _{$\beta\gamma$} and both G _{α} -GTP and G _{$\beta\gamma$} can interact with effector molecules and regulate their activity. Although, in principle, all G-protein families can signal through G _{$\beta\gamma$} subunits, this mode of signaling is most prevalent with signaling pathways regulated by G_{i1}, G_o, and G₁₂.

G-protein pathways are deactivated when G _{α} hydrolyzes GTP to GDP. In the GDP-bound form, G _{α} binds efficiently to G _{$\beta\gamma$} and restores the heterotrimer to its inactive state. The length of time that G _{α} is in its GTP-bound state determines the duration of the

signal. Regulators of G-protein signaling (RGS) bind to G _{α} and accelerate the rate of GTP hydrolysis by acting as GTPase activating proteins (GAPs). Thus, RGS proteins are important regulators of the timing of G-protein responses. Members of the G_i family are targets for RGS proteins.

Signaling through G _{$\beta\gamma$}

Many receptors coupled to G_i and G_o exert their effects through signals propagated to downstream effectors by G _{$\beta\gamma$} subunits. Similar to G _{α} subunits, G _{$\beta\gamma$} subunits regulate the activity of enzymes involved in the generation of second messengers. These are adenylyl cyclase, phospholipase C β , and phosphatidylinositol 3-kinase. G _{$\beta\gamma$} exhibits type-specific regulation of adenylyl cyclase, inhibiting some isoforms, but activating others synergistically with G _{α} . G _{$\beta\gamma$} activates certain isoforms of phospholipase C β , an enzyme that converts phosphatidylinositol into diacylglycerol and inositol trisphosphate. The second messenger inositol trisphosphate induces the release of calcium from intracellular stores, whereas diacylglycerol recruits protein kinase C to the plasma membrane. Phosphatidylinositol 3-kinase (PI3K) is also activated by G _{$\beta\gamma$} subunits. The generation of phosphatidylinositol 3,4,5-trisphosphate (PIP₃), the product of PI3K, mediates important cellular responses. Production of PIP₃ in white blood cells is an essential step in inducing the cells to migrate to sites of cell injury. PI3K activation by G _{$\beta\gamma$} is also associated with signaling pathways that regulate cell survival.

In addition to regulating second messengers, G _{$\beta\gamma$} subunits modulate the activity of numerous ion channels. The best characterized are potassium channels in the heart which slow heart rate when activated. G _{$\beta\gamma$} subunits bind directly to the channel and cause it to open (Figure 2). Certain voltage-gated calcium channels are inhibited by binding G _{$\beta\gamma$} subunits.

The effectors described above are regulated through direct binding of the G _{$\beta\gamma$} subunits. G _{$\beta\gamma$} is also an important regulator of mitogen-activated protein (MAP) kinase pathways. The direct target of G _{$\beta\gamma$} in these pathways has not been identified.

Gi

The founding member of the family, G_i , is named for its ability to inhibit the enzyme adenylyl cyclase. There are three forms of $G_{i\alpha}$, designated $G_{i\alpha1}$, $G_{i\alpha2}$, and $G_{i\alpha3}$, each encoded by a separate

Figure 1 Sequence comparison of $G_{i\alpha}$ family members. A nearest-neighbor dendrogram of $G_{i\alpha}$ family sequences. The scale bar represents a measure of evolutionary distances between the sequences analyzed.

gene. The three isoforms share many functions and will be considered together here. Heterotrimeric G_i couples to many different receptors, including those for catecholamines, neurotransmitters, and chemokines. Many of the effects associated with activation of G_i by receptors are mediated by $G_{\beta\gamma}$ subunits as discussed above. The best-characterized effector for $G_{i\alpha}$ is adenylyl cyclase. $G_{i\alpha}$ binds to this enzyme and inhibits its activity, thereby reducing intracellular levels of the second messenger cAMP (Figure 2). $G_{i\alpha}$ (and $G_{o\alpha}$) can propagate signals to protein kinases (e.g., the MAP kinase pathway or c-Src), but the direct target of $G_{i\alpha}$ in these pathways is unknown.

$G_{i\alpha}$'s are ubiquitously expressed and most cell types contain more than one form. Eliminating the gene for $G_{i\alpha1}$ or $G_{i\alpha3}$ in mice does not have any obvious effects on the organism's ability to develop or to reproduce. Mice lacking a functional gene for $G_{i\alpha2}$ appear to develop normally, but exhibit growth retardation, inflammatory bowel disease, and are prone to developing adenocarcinomas, demonstrating that $G_{i\alpha2}$ is essential for normal function of the intestine. The relatively mild phenotypes associated with inactivation of the individual

Figure 2 G_i signaling in the heart. In heart cells, the neurotransmitter acetylcholine elicits a slowing of the heart rate by activating a G_i -coupled signaling pathway. (a) In the basal state, $G_{i\alpha}$ is in the GDP-bound state and associated with $G_{\beta\gamma}$. The receptor is unoccupied and effectors (not shown) are inactive. (b) The neurotransmitter acetylcholine is released at the terminal of the vagus nerve that innervates the heart. Binding of acetylcholine activates the receptor, which, in turn, stimulates the release of GDP from $G_{i\alpha}$. GTP is present intracellularly at high concentration and quickly diffuses into the guanine-nucleotide-binding pocket on $G_{i\alpha}$. GTP binding induces a conformational change in $G_{i\alpha}$, causing it to dissociate from $G_{\beta\gamma}$. (c) $G_{i\alpha}$ -GTP interacts with adenylyl cyclase in the plasma membrane and inhibits its activity. $G_{\beta\gamma}$ subunits bind to the K^+ channel, causing it to open. The cell membrane becomes hyperpolarized, slowing action potential frequency and heart rate. (d) $G_{i\alpha}$ hydrolyzes its GTP to GDP to deactivate the pathway. The rate of GTP hydrolysis is accelerated by $G_{i\alpha}$ interaction with an RGS protein. Once in its GDP-bound state, $G_{i\alpha}$ reassociates with $G_{\beta\gamma}$ and the system is returned to the basal state.

Table 1 $G_{i\alpha}$ family members

Protein	Gene name	% Amino acid identity ^a	PTX substrate ^b	Fatty acylation ^c	Major tissue distribution
$G_{i\alpha 1}$	GNAI-1	100	Yes	Myr, palm	Nearly ubiquitous
$G_{i\alpha 2}$	GNAI-2	87	Yes	Myr, palm	Ubiquitous
$G_{i\alpha 3}$	GNAI-3	93	Yes	Myr, palm	Nearly ubiquitous
$G_{o\alpha A}$	GNAO	70	Yes	Myr, palm	Brain, neuroendocrine, heart
$G_{o\alpha B}$	GNAO	69	Yes	Myr, palm	Brain, neuroendocrine, heart
$G_{t\alpha f}$	GNAT1	67	Yes	Myr	Retinal rods
$G_{t\alpha c}$	GNAT2	69	Yes	Myr	Retinal cones
$G_{g\alpha}$	GNAT3	68	Yes	Myr	Taste buds
$G_{z\alpha}$	GNAZ	66	No	Myr, palm	Brain, adrenal, platelets, pancreas

$G_{i\alpha}$ genes probably reflect an ability of one $G_{i\alpha}$ subtype to compensate for the function of another.

G_o

$G_{o\alpha}$ is a close relative of the $G_{i\alpha}$'s, with 70% sequence identity to $G_{i\alpha 1}$ (Table 1). Two forms of $G_{o\alpha}$ ($G_{o\alpha A}$ and $G_{o\alpha B}$) are generated by alternative splicing of messenger RNA (mRNA). G_o is very abundant in the nervous system where it represents 0.5% of total membrane protein. It is also expressed in neuroendocrine tissues and, at low levels, in the heart. In general, receptors that are coupled to G_o bind neurotransmitters that mediate inhibitory, rather than excitatory, responses in the central nervous system. The best-studied effectors regulated by G_o are voltage-gated calcium channels, which are inhibited by $G_{\beta\gamma}$ subunits released upon receptor activation of G_o . Direct effectors of $G_{o\alpha}$ are not as well characterized. Inactivation of the $G_{o\alpha}$ gene in mice results in central nervous system dysfunction and abnormal regulation of calcium channels in the nervous system and heart.

G_z

$G_{z\alpha}$ is the most distantly related member of the $G_{i\alpha}$ family based on sequence comparison (Figure 1). Its expression pattern is more restricted than $G_{i\alpha}$, with abundant expression in brain, neuroendocrine tissues, and platelets. G_z has several properties that distinguish it from the other members of the G_i family. It is the only family member that is not a substrate for adenosine diphosphate (ADP)-ribosylation by pertussis toxin (see below). $G_{z\alpha}$ also has an intrinsic rate of GTP hydrolysis that is much slower than G_i or G_o . Thus, G_z pathways may be slow to turn off unless regulated by RGS proteins. $G_{z\alpha}$ interacts with several RGS family members that show marked specificity for $G_{z\alpha}$ over other G-protein α subunits. The complement of receptors that G_z responds to overlaps extensively with those that couple to $G_{i\alpha}$ and $G_{o\alpha}$. Given its abundant expression in brain, G_z is coupled to many neurotransmitters and can regulate ion channels, adenylyl cyclase, and MAP kinase pathways similar to G_i and G_o . $G_{z\alpha}$ -GTP binds directly to Rap1GAP, a GAP for the monomeric GTPase Rap1, an interaction that may modulate neuronal differentiation.

The gene for $G_{z\alpha}$ has been knocked out in mice. The $G_{z\alpha}$ -deficient mice develop normally and are fertile. However, they exhibit altered responses to psychoactive drugs and a mild impairment in platelet function. These phenotypes are consistent with the restricted distribution of $G_{z\alpha}$ in neural tissues and platelets. Mice deficient for $G_{z\alpha}$ also display increased pancreatic islet insulin secretion and correspondingly increased glucose clearance following glucose challenge, likely due to a constitutive increase in islet cAMP levels.

G_t (Transducin)

G_t is the G protein that mediates the visual signal transduction cascade. It is also known as 'transducin'. There are two closely related forms of $G_{t\alpha}$ that are encoded by separate genes. $G_{t\alpha p}$ is expressed in retinal rods, whereas $G_{t\alpha c}$ is found in cone cells. $G_{t\alpha p}$ and $G_{t\alpha c}$ both associate with specific $G_{\beta\gamma}$ complexes: $G_{t\alpha p}$ with $G_{\beta 1\gamma 1}$ and $G_{t\alpha c}$ with $G_{\beta 1\gamma 14}$. The receptor in the visual signal transduction cascade is rhodopsin, which harbors a covalently attached 11-*cis*-retinal. When a photon of light is absorbed by the retinal, it undergoes a *cis-trans* isomerization that induces a conformational change in rhodopsin. The activated receptor then promotes nucleotide exchange and subunit dissociation of G_t . $G_{t\alpha}$ -GTP propagates the signal by stimulating cGMP phosphodiesterase (PDE), an enzyme that hydrolyzes cGMP. PDE consists of two catalytic subunits and two inhibitory subunits (called PDE_{γ}). $G_{t\alpha}$ binds PDE_{γ} and relieves the inhibitory constraint on the catalytic subunits. Reduction of cellular levels of cGMP causes closure of cGMP-gated ion channels in the plasma membrane. This reduces the influx of Na^+ and Ca^{2+} , increasing the negative charge inside the cell, and causing the cell to become hyperpolarized. The net effect is a change in the signals that photoreceptors send to the brain.

An important mechanism for deactivating the phototransduction process is the hydrolysis of GTP by $G_{t\alpha}$. The intrinsic rate of GTP hydrolysis measured for $G_{t\alpha}$ *in vitro* is too slow to mediate the physiological response. *In vivo*, the GTPase rate of $G_{t\alpha}$ is accelerated by the GAP activity of a protein complex of the retinal RGS protein RGS9 and its binding partner $G_{\beta 5L}$. RGS9 has a G_{γ} -like domain that mediates its association with $G_{\beta 5L}$. The effector molecule PDE_{γ} also promotes GAP activity

by increasing the affinity of G_{α} for the RGS9/ $G_{\beta 5L}$ complex. Thus, timely inactivation of G_i is achieved through cooperation between RGS9- $G_{\beta 5L}$ and PDE $_{\gamma}$.

Mutations in the genes that encode $G_{\alpha_{tr}}$ and $G_{\alpha_{tc}}$ result in visual impairment in humans. A form of congenital night blindness is caused by a missense mutation in GNAT1 ($G_{\alpha_{tr}}$). Achromatopsia, also referred to as 'rod monochromacy', is an autosomal recessive disorder characterized by total colorblindness, low visual acuity, photophobia, and involuntary eye movement. GNAT2 ($G_{\alpha_{tc}}$) is the third gene identified with mutations associated with this disorder.

G_g (Gustducin)

G_g is a signal transducer for signaling pathways that mediate taste. Its expression is restricted primarily to taste buds. $G_{g\alpha}$ is closely related to $G_{\alpha_{tr}}$ and $G_{\alpha_{tc}}$ (Figure 1). Gustducin is important in recognition of sweet, bitter, and umami, the taste associated with savory meat. G_g couples receptors for bitter and sweet tastants to specific taste cell PDEs. Transducins and gustducins therefore share a common family of effectors. Taste receptors also elicit the activation of phospholipase C- $\beta 2$ through the action of $G_{\beta\gamma}$ subunits. In mice deficient for $G_{g\alpha}$, the animals show impaired responses to bitter and sweet agents and umami, but are normal in their responses to sour and salty tastants. Thus, animals use a different signal transduction pathway to experience sour and salty taste.

Posttranslational Modifications

Members of the G_i family are subject to a number of posttranslational modifications (Table 1). All family members except $G_{\alpha_{zz}}$ are modified with ADP-ribose at a cysteine residue near the C-terminus by a bacterial toxin from *Bordetella pertussis*. The C-terminus of G_{α} is an important site of interaction with G-protein-coupled receptors. Modification of G_{α} with the bulky ADP-ribose group interferes with receptor-G-protein coupling. Therefore, cells treated with pertussis toxin cannot respond to ligands that bind to G_i -coupled receptors. Pertussis toxin has been a useful experimental tool to define cellular responses that are mediated by members of the G_i family.

All G-protein α subunits are modified with fatty acids at or near the amino terminus. Fatty acylation provides a hydrophobic anchor that mediates binding to the plasma membrane. Members of the G_i family (but not G_s , G_{12} , or G_q families) are N-myristoylated. Myristic acid is added through an amide linkage to a glycine residue exposed after removal of the

initiator methionine. This is the only modification found on $G_{\alpha_{tr}}$ and $G_{\alpha_{g\alpha}}$. However, $G_{\alpha_{tr}}$, $G_{\alpha_{g\alpha}}$, and $G_{\alpha_{zz}}$ undergo a second type of fatty acylation, S-palmitoylation, which occurs at a cysteine residue adjacent to the N-myristoylated glycine. Whereas N-myristoylation is a stable modification, S-palmitoylation is reversible and can be regulated.

Heterotrimeric G proteins are generally not regulated by protein phosphorylation and dephosphorylation, in contrast to many signaling proteins. $G_{\alpha_{zz}}$ is an exception. It is phosphorylated by protein kinase C and p21-activated kinase 1. Phosphorylation of $G_{\alpha_{zz}}$ reduces its ability to bind $G_{\beta\gamma}$ and interact with RGS proteins, thereby prolonging $G_{\alpha_{zz}}$ activation.

Glossary

Anaplerotic reactions Enzymatic reactions that produce citric acid cycle anions to replace those that leave the cycle for the synthesis of compounds such as glucose and fatty acids. The major anaplerotic enzyme is pyruvate carboxylase.

Cataplerotic reactions Enzymatic reactions that remove citric acid cycle anions from the mitochondria for biosynthetic processes (i.e., gluconeogenesis) to insure the balance of intermediates in the cycle. The major cataplerotic enzyme is phosphoenolpyruvate carboxykinase.

Cori cycle Process in which the lactate generated in the red blood cells and muscle is converted into glucose in the liver and cycled back to these tissues for reconversion into lactate.

Gluconeogenesis The *de novo* synthesis of glucose from nonhexose precursors.

Ketone bodies Water-soluble fuels produced by the liver from the acetyl coenzyme A (CoA) that is generated from the β -oxidation of fatty acids. The three ketone bodies, acetoacetate, β -hydroxybutyrate, and acetone, accumulate in the blood of mammals during periods of fasting.

Lipolysis The degradation of triglyceride to free fatty acids and glycerol; this occurs primarily in the white adipose tissue.

Proteolysis The breakdown of proteins to their component amino acids.

β -Oxidation The oxidation of fatty acids to acetyl CoA in the mitochondria.

History

Claude Bernard first noted the synthesis of glucose in his famous description of glucose turnover during fasting. However, it is the work of Carl and Gerty Cori that established gluconeogenesis as critical for the synthesis of glucose from lactate as part of what is now known as the Cori cycle. Gluconeogenesis is not a reversal of glycolysis, although the two pathways share a number of enzymes. A major advance in the understanding of the specific reactions in the pathway of glucose synthesis took place when Merton Utter and his colleagues discovered two of the major enzymes of the pathway, phosphoenolpyruvate carboxykinase (PEPCK) and pyruvate carboxylase (PC). In the 1960s and 1970s, the research of Hans Krebs, Charles Park and John Exton, John Williamson and Henry Lardy, among others, set out the metabolic parameters of the pathway as it is known today. Finally, the elevated rate of synthesis and release of glucose by the liver and kidney cortex during diabetes mellitus is a major factor in the pathogenesis of this disease.

Overview of Gluconeogenesis

Gluconeogenesis is defined as the *de novo* synthesis of glucose from nonhexose precursors. Gluconeogenesis does not include the conversion of fructose or galactose into glucose in the liver or the generation of glucose from glycogen via glycogenolysis. The pathway of gluconeogenesis ([Figure 1](#)) occurs mainly in the liver and kidney cortex and to a lesser extent in the small intestine. The major substrates for gluconeogenesis include lactate, pyruvate, propionate, glycerol, and 18 of the 20 amino acids (the exceptions are leucine and lysine). Glucose cannot be synthesized from fatty acids, since they are converted by β -oxidation into acetyl coenzyme A (CoA), which subsequently enters the citric acid cycle and is oxidized to CO₂.

[†]Deceased.

The three-carbon fatty acid, propionate, is an exception since it is carboxylated, converted into succinyl-CoA, and enters the citric acid cycle as a four-carbon intermediate, not as acetyl CoA; acetone, which can be converted into propanediol, is a very minor gluconeogenic precursor. In addition, the last three carbon atoms of the odd-chain fatty acids generate propionyl CoA during β -oxidation and are thus partly gluconeogenic. There are 14 enzymes involved in the conversion of lactate into glucose; three of these enzymes are classified as gluconeogenic (PEPCK, fructose-1,6-bisphosphatase (FBPase), and glucose-6-phosphatase (G6Pase)) and one is anaplerotic (PC), since it is important in both gluconeogenesis and lipogenesis. The remainder of the pathway is simply a reversal of the enzymes of glycolysis, which is responsible for the breakdown of glucose. Gluconeogenic enzymes are present in the cytosol, mitochondria, and endoplasmic reticulum (ER) of the tissues in which this pathway is present. Net gluconeogenesis occurs during starvation and after a meal high in fat and protein without carbohydrate.

The Enzymes of Gluconeogenesis

The unique properties of gluconeogenesis are attributable to the one anaplerotic and the three gluconeogenic enzymes in the pathway. The following discussion describes each of these enzymes and reviews their regulatory properties.

Pyruvate Carboxylase

PC is found in the mitochondria and catalyzes the following reaction:

PC is a multisubunit enzyme that has acetyl CoA as a positive allosteric regulator. The enzyme is critical for both gluconeogenesis and fatty acid synthesis, since it provides oxalacetate which is a precursor of malate and citrate, two citric acid cycle

Figure 1 The pathway of hepatic gluconeogenesis. The figure demonstrates the reactions involved in gluconeogenesis in the liver starting with alanine, lactate, or serine as precursors. The movement of aspartate and malate from the mitochondria is also indicated to demonstrate the redox state balance that occurs between the mitochondria and the cytosol during gluconeogenesis.

intermediates that leave the mitochondria as part of biosynthetic processes. Since it is essentially irreversible under physiological conditions, PC does not generate pyruvate from oxalacetate. PC is generally considered an anaplerotic (Greek: to fill up) enzyme since it functions to replace the oxalacetate that is reduced to malate in the citric acid cycle and used in the synthesis of glucose. Since citric acid cycle intermediates are important in both gluconeogenesis and lipogenesis, PC plays a role in both the pathways.

Phosphoenolpyruvate Carboxykinase

PEPCK catalyzes the following reaction:

It is found in both the mitochondria (PEPCK-M) and the cytosol (PEPCK-C). Two different nuclear genes encode these two isoforms of PEPCK. Expression of the gene PEPCK-C is inducible by diet and hormones, while PEPCK-M is largely constitutive.

Species vary in the amount of the two isoforms expressed in gluconeogenic tissues. Rodent species such as the rat and mouse have 90% PEPCK-C in their liver and kidney cortex, while adult birds have 100% PEPCK-M. Humans and most other mammalian species studied to date have 50% of both isoforms. The exact metabolic significance of having two isoforms of PEPCK is not entirely clear but it has been proposed that PEPCK-M allows the direct synthesis of PEP in the mitochondria, thus bypassing the need to transport reducing equivalents out of the mitochondria. This point is discussed in more detail later. It is important to note that while PEPCK is a gluconeogenic enzyme, it is also involved in the synthesis of 3-glycerol phosphate from citric acid cycle intermediates for the synthesis of triglyceride in a process termed 'glyceroneogenesis'. In this regard, PEPCK is a cataplerotic enzyme, since it removes citric acid cycle anions that could accumulate when the carbon skeletons of amino acids enter the mitochondria for further metabolism. Thus, anaplerosis is balanced by cataplerosis to insure the appropriate level of citric acid cycle anions.

Despite the fact that PEPCK is a key enzyme in gluconeogenesis, it has no known allosteric regulators. However, recent studies have shown that PEPCK-C is acetylated at several lysines, one at a residue near the active site, which increases the activity of the enzyme; the importance of this covalent modification in the enzyme in its overall regulation of gluconeogenesis remains to be established. PEPCK-C has a relatively short half-life of 6 h and alterations in the rate of gene transcription are rapid. For example, the rate of PEPCK-C gene transcription in the liver is increased 10-fold in 30 min after the administration of cyclic adenosine monophosphate (cAMP) to animals. Insulin administration causes an equally rapid decrease in the transcription of the gene. It has thus been suggested that the level of enzyme protein in the liver is a critical determinant in the overall activity of the enzyme. Transcription of the gene for PEPCK-C has been studied in considerable detail, and many of the transcription factors that regulate the tissue-specific expression of the gene have been identified. A detailed discussion of this area is beyond the scope of this article but the reader is directed to several reviews on the subject listed in the section Further Reading.

Fructose-1,6-Bisphosphatase

FBPase is found in the cytosol. In mammalian liver, the enzyme is a homotetramer with a subunit molecular weight of 38–41 kDa, depending on the species. FBPase catalyzes the following reaction:

The enzyme is regulated allosterically by a number of small molecules including AMP and fructose-2,6-bisphosphate, which are negative regulators, and adenosine triphosphate (ATP) that is a positive regulator. The enzyme is also covalently modified by phosphorylation by cAMP-dependent protein kinase (PKA), which decreases its activity. The concentration of fructose-2,6-phosphate is determined by a unique bifunctional enzyme, 6-phosphofructo-2-kinase-2,6-bisphosphatase, which, when phosphorylated by protein kinase A, functions as a phosphatase and converts fructose-2,6-phosphate into fructose-6-phosphate, thereby lowering the concentration of this key allosteric regulator. This has the effect of decreasing flux through the glycolytic enzyme, phosphofructokinase, while increasing the activity of FBPase, since fructose-2,6-phosphate is a negative regulator of that enzyme. This type of reciprocal regulation of enzymes that share common intermediates is critical in controlling the rate of futile cycling in the pathways of glycolysis/gluconeogenesis, since it insures carbon flow toward the synthesis of glucose during fasting and toward pyruvate (glycolysis) when dietary carbohydrate is available.

Glucose-6-Phosphatase

The role of this enzyme in the synthesis of glucose was first suggested by the Coris in 1938 and finally demonstrated by Marjorie Swanson in the United States and Christian deDuve and colleagues in Belgium in the early 1950s.

G6Pase is a multisubunit enzyme that is present in the ER of the liver, kidney cortex, and small intestine, and comprises

several integral membrane proteins: the catalytic subunit (G6PaseC) and transporters for glucose-6-phosphate (for transport into the ER) and inorganic phosphate and glucose (GLUT2) for transport out. Pancreatic islets contain an isoform of G6PaseC, termed G6PaseC2, which is 50% identical with G6PaseC; while its function is not definitively established (the pancreas does not make and release glucose), it is suggested to be involved in glucose sensing by the β -cells of the pancreas. A third isoform, called G6PaseC3, which is 30% identical with G6PaseC, was recently identified and shown to be present in a number of mammalian tissues. Its metabolic role is not clear at present.

G6Pase is not solely a gluconeogenic enzyme, since it also functions as the last step in glycogenolysis, releasing glucose from the liver into the blood. Thus, mutations in any of the enzymes in the multienzyme alter not only gluconeogenesis but also glycogenolysis. Glycogen storage disease 1a (commonly called von Gerke's disease) is a mutation in the gene for G6PaseC, while glycogen-storage disease 1b involves mutations in the gene for the glucose-6-phosphate transporter. Mutations in the genes for this multisubunit complex result in profound hypoglycemia during the postabsorptive state and lactic acidemia, among other severe metabolic defects in hepatic and renal function.

Factors that regulate the expression of the gene for G6PaseC have been studied in detail. The activity of the enzyme can be induced by starvation, cAMP, fatty acids, and glucocorticoids. Somewhat paradoxically, glucose at high concentrations also stimulates transcription of the gene for this enzyme. It has been suggested that the induction of G6Pase gene transcription by glucose may prevent excessive hepatic glucose storage as glycogen.

Physiological Control of Gluconeogenesis

Dietary Status Determines the Extent of Gluconeogenesis

There are two normal metabolic situations during which gluconeogenesis occurs in mammals. In addition, gluconeogenesis increases during diabetes, resulting in an increased rate of glucose output by the liver. The first physiological situation involves the gluconeogenesis, characteristic of starvation, and, the second, the gluconeogenesis, that occurs after a meal that contains minimal carbohydrate. During starvation, the source of carbon for gluconeogenesis is body protein, largely from the muscle and lactate and pyruvate from glycolysis and glycerol from lipolysis. The muscle undergoes proteolysis, largely due to the fall in insulin. Proteolysis in muscle results in the generation of 20 amino acids. However, reactions in the muscle convert these amino acids mainly into alanine and glutamine, which are leased for subsequent metabolism. Both alanine and glutamine can be converted into glucose in the liver but in starvation it is the kidney cortex that utilizes glutamine. The kidney synthesizes glucose from the carbon skeleton of glutamine and uses the ammonia derived from this process to maintain the acid–base balance of the tubular urine. Later in this article, the metabolic role of renal gluconeogenesis is discussed in detail. The gluconeogenesis that occurs after a meal containing protein and fat, without carbohydrate, involves the 18 gluconeogenic amino acids found in dietary protein

(degradation of the amino acids leucine and lysine contributes no carbon for glucose synthesis). The carbon skeletons of most of the amino acids enter the citric acid cycle, proceed forward to malate, and are subsequently converted into glucose via the gluconeogenesis as described in detail below.

The Role of Fatty Acid Oxidation in the Control of Gluconeogenesis

Gluconeogenesis occurs during fasting but the amount of glucose supplied by this process is far less than can be generated by glycogenolysis during the immediate postabsorptive period. Blood glucose homeostasis is possible only because other substrates (fatty acids and ketone bodies) are used as fuels by peripheral tissues, thus sparing the use of glucose. In general, the rate of gluconeogenesis is increased in the liver during starvation due to a fall in the concentration of insulin and a rise in glucagon; glucocorticoids play a permissive role in stimulating this process. This change in hormone status results in profound alterations in the metabolism of both skeletal muscle and adipose tissue. There is an increased rate of lipolysis in the adipose tissue and a net protein breakdown (proteolysis) in muscle. This results in an elevated rate of delivery of fatty acids to the liver from adipose tissue and primarily alanine from muscle. Fatty acid oxidation by hepatic mitochondria raises the concentration of acetyl CoA and shifts the redox state of that organelle toward reduction; there is a concomitant increase in ATP synthesis. In the rat, for example, the hepatic nicotinamide adenine dinucleotide (NAD)/NADH ratio shifts from 700 to 550 after 48 h of starvation. The net effect of this increase in fatty acid oxidation is a stimulation of gluconeogenesis and an inhibition of glycolysis. This stimulatory effect is exerted at several levels. First, the rise in NADH and ATP inhibits multiple steps in the citric acid cycle, including citrate synthase, isocitrate dehydrogenase, and α -ketoglutarate dehydrogenase complex. Most importantly, the increased concentrations of ATP, NADH, and acetyl CoA that occur in the liver during fasting inhibit flux through the pyruvate dehydrogenase complex. The importance of the latter step is emphasized upon subsequently.

The Pathway of Gluconeogenesis

During starvation, alanine is transported from the muscle to the liver, where it is converted into pyruvate. As mentioned above, during fasting the pyruvate dehydrogenase complex is inhibited by the products of fatty acid oxidation. At the same time, acetyl CoA activates PC, thus converting pyruvate into oxalacetate, which is then reduced to malate by the mitochondrial isoform of NAD malate dehydrogenase. Malate leaves the mitochondria and is oxidized to oxalacetate via the cytosolic isoform of NAD malate dehydrogenase; the oxalacetate is decarboxylated to PEP by PEPCK-C, and the PEP is further metabolized via a reversal of glycolysis to fructose-1,6-bisphosphate. This intermediate is then converted into fructose-6-phosphate by the gluconeogenic enzyme, FBPase. Finally, G6Pase, which is present in the ER, generates free glucose from glucose-6-phosphate; GLUT2 transports the glucose from the liver to the blood.

Redox Balance for Gluconeogenesis

It is important to note that gluconeogenesis requires two molecules of NADH for every molecule of glucose that is synthesized. The NADH is required to reverse the glyceraldehyde-3-phosphate dehydrogenase reaction. The source of this NADH varies according to the substrate used for gluconeogenesis. When oxidized compounds such as pyruvate and alanine are used for glucose synthesis, the pathway involves malate transport from the mitochondria, essentially generating reducing equivalents in the cytosol for gluconeogenesis, as described above. There is a slight variation in this pathway of glucose synthesis when the starting substrate is lactate. In this case, the conversion of lactate into pyruvate in the cytosol generates NADH, which obviates the necessity of transporting malate from the cytosol to produce NADH. There are two possible routes for the movement of intermediates from the mitochondria that is not linked to the transport of reducing equivalents. The first involves the transamination of mitochondrial oxalacetate to aspartate via aspartate aminotransferase. The aspartate is transported to the cytosol and converted into oxalacetate by the cytosolic isoform of aspartate aminotransferase (Figure 1). The second variation in metabolite transfer involves the generation of oxalacetate in the mitochondria via PC, followed by the synthesis of PEP directly in the mitochondria via PEPCK-M. PEP is readily transported from the mitochondria on the tricarboxylate carrier in the inner mitochondria membrane. This role of PEPCK-M in avian metabolism supports the physiological role of the two isoforms of PEPCK. In birds, the liver uses only lactate for gluconeogenesis, and the avian liver contains only PEPCK-M; gluconeogenesis from amino acids occurs in the kidney.

Regulation of Gluconeogenesis

Gluconeogenesis is regulated at a few fundamental levels, which are discussed in the following.

Substrate Delivery to the Liver and Kidney

The rate of delivery of substrates such as lactate, which is derived from glycolysis in skeletal muscle (Cori cycle) or glycolysis in erythrocytes, glycerol from the breakdown of triglycerides in adipose tissue, and amino acids from proteolysis in skeletal muscle and other protein-rich tissues, greatly influences the level of hepatic gluconeogenesis. Thus, the control of the release and delivery of precursors from peripheral tissues is an important controlling factor in the rate of gluconeogenesis in the liver and kidney cortex. For example, insulin controls the rate of gluconeogenesis, in part, by regulating the delivery of substrates from muscle and adipose tissue to the liver.

Mass Action Regulation of Enzymes

As an example of this type of regulation, the activity of glyceraldehyde-3-P dehydrogenase (in the direction of gluconeogenesis) is stimulated by a rise in NADH in cytosol (the NAD/NADH ratio). The activity of G6Pase is increased by a rise in the concentration of G6Pase, and PEPCK activity is stimulated by a rise in the concentration of oxalacetate.

Allosteric Activation of Key Enzymes

As an example of this type of regulation of gluconeogenesis, acetyl CoA allosterically activates PC, while FBPase is activated by ATP and inhibited by AMP and fructose-2,6-bisphosphate. In addition, during gluconeogenesis, pyruvate kinase must be inhibited in order to prevent the conversion of PEP back to pyruvate (futile cycling) by liver-type pyruvate kinase (PK-L). A rise in the concentration of alanine or ATP and a decrease in the level of fructose-1,6-bisphosphate that occurs in the liver during fasting result in the allosteric inhibition of the activity of this enzyme (Figure 2).

Covalent Modification

Phosphorylation of gluconeogenic enzymes by PKA regulates the rate of key steps in gluconeogenesis. PK-L (not the muscle isozyme, PK-M) is inhibited by cAMP-induced phosphorylation via PKA. This, together with the allosteric regulation mentioned above, prevents the conversion of PEP into pyruvate in the liver and thus limits possible futile cycling of carbon and resulting energy loss. Despite this coordinated regulation, it has been estimated that about 25% of the carbon recycles at that step. The PKA regulation of hepatic gluconeogenesis is controlled in part by changes in the concentration of fructose-2,6-bisphosphate. As mentioned above, this compound allosterically regulates two critical enzymes, phosphofructokinase (the rate-controlling enzyme in glycolysis) and FBPase (the key gluconeogenic enzyme). Fructose-2,6-bisphosphate is both synthesized and degraded by a single, bifunctional enzyme 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase, which can act as a kinase (it synthesizes fructose-2,6-bisphosphate using ATP as a source of phosphate) or as a phosphatase (it converts fructose-2,6-bisphosphate into fructose-6-phosphate plus inorganic phosphate). Phosphorylation of this enzyme by PKA induces the phosphatase function of the enzyme. This results in a decrease in the concentration of fructose-2,6-bisphosphate, thereby inhibiting the activity of phosphofructokinase (the rate-limiting enzyme in glycolysis), which requires fructose-2,6-bisphosphate as an allosteric activator and stimulating the activity of FBPase, for which fructose-2,6-bisphosphate is an inhibitor (Figure 2). Thus, the covalent modification of the bifunctional enzyme has a reciprocal effect on the gluconeogenesis (stimulation) and glycolysis (inhibition).

Alteration in Gene Expression

The expression of several of the genes in the gluconeogenic pathway is modified by starvation, diabetes, or by diets rich in carbohydrate. Transcription of the genes coding for PEPCK-C, FBPase, and G6Pase is increased by fasting and during diabetes, while transcription of the genes for several of the glycolytic enzymes, such as PK-L, phosphofructokinase, and glucokinase, is decreased. Alterations in the rate of gene transcription change the levels of messenger RNA (mRNA) for a specific enzyme, resulting in a change in the rate of synthesis for the enzyme. An increase or decrease in enzyme content usually occurs over a period of several hours and is mediated by hormones such as glucagon (acting via cAMP), insulin, and glucocorticoids that stimulate the transcription of the genes for

Figure 2 Regulation of potential futile cycles during gluconeogenesis. (a) The control of the oxaloacetate/PEP/pyruvate futile cycle. The enzymes shown in this panel include: (1) pyruvate carboxylase, (2) PEP carboxykinase, and (3) liver-type pyruvate kinase. This cycle is regulated by inhibition of liver-type pyruvate kinase by allosteric regulation by alanine and ATP and by phosphorylation of the enzyme by PKA. In addition, the decreased glycolytic flux that occurs during periods of gluconeogenesis (starvation) reduces the concentration of fructose-6-phosphate, a positive allosteric regulator of liver-type pyruvate kinase. (b) The control of the fructose-1,6-bisphosphate/fructose-6-phosphate futile cycle. The enzymes shown in this panel include: (1) phosphofructokinase and (2) fructose-1,6-bisphosphatase (FBPase). Phosphofructokinase is activated by AMP and fructose-2,6-bisphosphate and inhibited by ATP, while fructose-1,6-bisphosphatase is regulated in the opposite manner by the same intermediates. The result is a coordinated control of carbon flux via glycolysis and gluconeogenesis in the liver.

these enzymes. Metabolites such as glucose and fatty acids also exert control of the expression of specific genes involved in their metabolism. Several of the references listed in the section Further Reading review the details of the control of transcription of genes involved in gluconeogenesis.

Renal Gluconeogenesis

The synthesis of glucose in the kidney cortex is directly related to the loss of ketone bodies in the urine. During periods of fasting, the kidney excretes large amounts of ketone bodies (weak acids), but produces urine that is near neutrality. The relative acidity of the tubular urine is maintained at about pH 6.0 by the generation of ammonia from the metabolism of glutamine that has been mobilized from the muscle during starvation. Glutamine is converted into glutamate by glutaminase and glutamate to α -ketoglutarate by NAD glutamate dehydrogenase; this generates two molecules of ammonia that are released into the urine to maintain the neutrality of the urine. The α -ketoglutarate is then converted into glucose. Thus, ammoniogenesis in the kidney is linked to gluconeogenesis (Figure 3). Interestingly, acidosis induces transcription of the gene for PEPCK-C, increasing its concentration in the kidney cortex. This elevation in the activity of PEPCK-C is critical for the increased rates of gluconeogenesis noted during acidosis.

Figure 3 Gluconeogenesis from glutamine in the kidney. Glutamine from the muscle is metabolized by the kidney cortex to generate ammonia (circled) that is used to titrate the acidity of the tubular urine. This involves two enzymatic reactions, both of which are in the renal mitochondria, (1) glutaminase and (2) NAD glutamate dehydrogenase. The α -ketoglutarate, produced by the removal of the two amino groups of glutamine, enters the citric acid cycle, is oxidized to malate, and then proceeds to glucose via gluconeogenesis. The large circle in the figure represents the renal mitochondria.

Final Words

Glucose oxidation is essential for human metabolism and thus gluconeogenesis is a critical element in the maintenance of glucose homeostasis in all mammals. In humans, this process is continuous and augmented after the depletion of liver glycogen. Gluconeogenesis is the sole source of glucose during starvation. Since gluconeogenesis from amino acids results in a depletion of lean body mass, a number of metabolic accommodations occur to minimize the use of glucose by tissues such as the brain and skeletal muscle (fuel sparing). The details of these processes appear elsewhere in this encyclopedia. However, available data from human studies suggest that the rate of hepatic gluconeogenesis does not change appreciably in nondiabetic individuals; the mechanisms for this conclusion are presently not clear. A dysfunction in gluconeogenesis is a critical element in diabetes, a disease that is increasing at an alarming rate worldwide. Drugs aimed at inhibiting specific steps in gluconeogenic pathway hold promise in blocking the markedly elevated rate of hepatic glucose output that occurs in

this disease due in part to increased glucose synthesis by the process discussed in detail in this article. It is impossible to reference all of the research responsible for our understanding of the pathway of gluconeogenesis and its regulation. A select number of more general articles that reflect the field are included in the section Further Reading.

Glossary

Active transport A process requiring input of energy where solute is generally accumulated against a concentration gradient.

Alternating access A mechanism in which both co-substrate-binding sites are exposed alternatively to the each side of the membrane by reciprocal opening and closing of outward- and inward-facing cavities.

Electrochemical ion gradient ($\Delta\tilde{\mu}_X^Z$; where X is an ion and Z is its valence) An electrochemical ion concentration gradient across a membrane is composed

of an electrical potential (ΔY) and a chemical concentration gradient (ΔY) (e.g., $\Delta\tilde{\mu}_{H^+}$ is composed of a ΔY and a pH).

Primary active transport Chemical energy or light is used directly to energize pumping of solute.

Secondary active transport Free energy stored in an electrochemical ion gradient is transduced into a solute concentration gradient.

Symport Two co-substrates are transported across the membrane in a same direction.

Symporter A transport protein that catalyzes symport.

Sugar transport in bacteria involves highly specific membrane proteins that catalyze translocation and accumulation of various sugars from the outside environment across the cytoplasmic membrane and into the cell where they are metabolized. As with other membrane proteins that catalyze transport of metabolites other than sugars, these proteins are called porters, permeases, or carriers. When energy is involved in the transport, the process is called active transport. In bacteria, there are three types of active transport systems involved in sugar transport, and each one utilizes different energy sources.

The Phosphoenolpyruvate: Sugar Phosphotransferase System

Classification

According to the Transport Commission (TC) classification, the phosphotransferase system (PTS) represents a distinctive family found only in certain bacteria. It is a bacterial sugar transport system, which also plays an essential role in the phenomena of catabolite repression and inducer exclusion, particularly in *Escherichia coli* (*E. coli*) and *Salmonella typhimurium*.

Functional Properties

The PTS is a multicomponent system that catalyzes vectorial phosphorylation of various sugars. In *E. coli*, glucose and other sugars are translocated across the membrane by PTS-catalyzed vectorial phosphorylation (Figure 1) (i.e., glucose from outside appears in the cytoplasm as glucose-6-phosphate). Therefore, translocation across the membrane and the first step in metabolism are one and the same. Many sugars are transported by PTS systems (glucose, mannitol, fructose, mannose, galactitol, sorbitol, xylitol, and *N*-acetylglucosamine), and specificity for each sugar is provided by the membrane-embedded component of the system. In *E. coli*, only monosaccharides and their derivatives are substrates for PTS systems, but in other bacteria, this type of system also utilizes disaccharides.

The PTS is also involved in regulating uptake and metabolism of many other sugars, as discussed here, as well

as bacterial chemotaxis toward these sugars, which is not covered here.

Assembly and Phosphoryl Transfer Reaction

The PTS includes three essential enzymes, termed Enzyme I (EI), Enzyme II (EII), and Histidine protein (HPr) (Figure 1). EI is a soluble protein kinase encoded by *ptsI* gene that catalyzes the phosphorylation of HPr from phosphoenolpyruvate (PEP). HPr, encoded by the *ptsH* gene, is a small monomeric protein that is phosphorylated on a histidine residue at position 15. Both proteins are involved only in phosphoryl transfer reactions and are not sugar specific. PEP autophosphorylates EI on His189, and the phosphoryl group is sequentially transferred to HPr. EII consists of three functional domains – IIA, IIB, and IIC. The organization of these domains depends on the specific sugar transported. In the case of glucose transport in *E. coli* (Figure 1), IIA^{Glc} , encoded by the *crr* gene, exists as a separate polypeptide, which enables it to perform multiple functions. IIA^{Glc} receives a phosphoryl group at His90 from HPr and transfers the phosphoryl group to Cys421 of IIB^{Glc} , which is a part of the membrane protein complex $IIBC^{Glc}$ (Figure 1). IIB^{Glc} directly donates the phosphoryl group to sugar to catalyze translocation across the membrane. IIC^{Glc} consists of multiple transmembrane helices and is likely responsible for allowing access of the sugar to IIB^{Glc} for phosphorylation and release on the inner surface of the membrane (i.e., vectorial phosphorylation). With some PTS systems in *E. coli*, the three domains are contained within a single polypeptide (e.g., mannitol) or domains IIA and IIB are in a single polypeptide, but domain C consists of two polypeptides (e.g., mannose).

Preferential Utilization of Carbohydrate

In *E. coli*, there is a preferential growth on glucose via the PTS in the presence of several sugars (diauxie). This phenomenon involves regulatory functions of the PTS with respect to transcription of a wide variety of inducible proteins that are

Figure 1 The glucose PTS system in *E. coli*. Shown is the sequence of phosphoryl transfer reactions through $\text{PEP} \rightarrow \text{EI} \rightarrow \text{HPr} \rightarrow \text{EIIA} \rightarrow \text{EIIB}$ domain $\rightarrow$ glucose during vectorial phosphorylation across the membrane through the EIIC domain. Glucose enters the cells as glucose-6-phosphate. Dephosphorylated IIA^{Glc} binds to non-PTS permeases – MalK in MalEFGK₂ (PDB ID:2r6g), LacY (2v8n), and MelB – and inhibits transport of non-PTS sugars.

dependent upon cyclic-AMP (cAMP; catabolite repression), as well as regulation of the activity of endogenous levels of inducible permeases (inducer exclusion). Both regulatory activities are properties of EIIA^{Glc} . In the presence of glucose, the steady-state level of phosphorylated enzyme IIA^{Glc} is low, which leads to decreased adenylate cyclase activity, low intracellular levels of cAMP, and low levels of the catabolite receptor protein–cAMP complex. Therefore, when glucose is present, transcription cannot be activated for most inducible PTS systems and non-PTS sugar permeases.

Another way to ensure preferential utilization of glucose is by inducer exclusion (Figure 1). In the presence of glucose, not only is the expression level of inducible transport systems dramatically reduced due to decreased transcription, but also the activity of the non-PTS sugar permeases expressed at basal levels is inhibited by binding of unphosphorylated IIA^{Glc} . These proteins include lactose permease (LacY), melibiose permease (MelB), and MalK (a component of the maltose transport complex). For example, with LacY, binding of IIA^{Glc} blocks entry of lactose and subsequent formation of allolactose, the true inducer of the lactose operon.

Electrochemical Cation-Gradient-Driven Symporters

Classification

Most cation gradient-driven symporters that catalyze sugar transport belong to the large, ancient, and diverse major facilitator superfamily (MFS), members of which are found ubiquitously in all living organisms. Within the MFS, the sugar porter family (e.g., galactose permease and arabinose permease), the oligosaccharide/proton symporter family (e.g., LacY and

sucrose permease), and the glycoside–pentoside–hexuronide: cation symporter family (e.g., MelB) are major subfamilies involved in bacterial sugar transport. In addition, the solute sodium symporter (SSS) family (e.g., sodium/galactose transport (SgIT)) also catalyzes monosaccharide accumulation.

Structural Features

Cation gradient-driven symporters involved in sugar transport are composed of a single polypeptide with 12–14 membrane-spanning helices, and for those studied intensively, a single polypeptide is able to catalyze translocation and accumulation. X-ray crystal structures of LacY from *E. coli* indicate that the protein is pseudo-symmetrically organized by the N- and C-terminal six-helix bundles (Figure 2(a)). A large central internal hydrophilic cavity in LacY is open to the cytoplasm, closed to the periplasm, and extends halfway into the membrane. Both sugar- and H^+ -binding sites lie at the apex of the cavity in the approximate middle of the protein. The inward-facing conformation represents the major population of LacY in the membrane, and the fold is postulated to represent most members of the MFS. The X-ray crystal structure of a SgIT from *Vibrio parahaemolyticus*, a member of the SSS family, reveals a different overall fold (Figure 2(b)), which contains an inverted repeat of five-transmembrane helices, a common structural core shared by many other genetically unrelated Na^+ symporters.

Functional Properties

The sugar permeases in the MFS or SSS families catalyze the transport of the mono- and disaccharides and their derivatives. They do not utilize PEP or adenosine triphosphate (ATP), but are driven by the free energy released from the energetically downhill movement of a cation (H^+ , Na^+ , or Li^+) in response to an electrochemical ion gradient to catalyze sugar translocation across the membrane. Unlike the PTS, with cation-gradient-driven transport, sugar enters the cell in an unchanged form and accumulates inside the cell against a concentration gradient and/or is metabolized. Mechanistically and thermodynamically, it is noteworthy that MFS or SSS sugar permeases catalyze sugar/ion symport in both directions across the membrane (influx and efflux), unlike the other transport systems described. An alternating access model describes the overall conformational change during transport: both co-substrate binding sites are exposed alternatively to the each side of the membrane by reciprocal opening and closing of outward-facing and inward-facing cavities. Turnover occurs only when co-substrate binding sites are concurrently occupied.

Representatives

LacY

LacY, encoded by the *lacY* gene of the *lac* operon, consists of 417 amino acid residues and is solely responsible for all the translocation reactions catalyzed by the β -galactoside transport system in *E. coli*. LacY is a particular well-studied representative of the oligosaccharide/ H^+ symport family of the MFS. Like many other MFS transporters, LacY utilizes free energy released from the downhill translocation of H^+ in response to an electrochemical H^+ gradient ($\Delta\mu_{\text{H}^+}$: interior negative and/or alkaline) to drive the stoichiometric translocation of a

galactopyranoside. In the absence of the electrochemical proton gradient, LacY catalyzes the converse reaction, utilizing free energy released from downhill translocation of sugar to drive uphill stoichiometric transport of H^+ . Intracellular β -galactosidase catalyzes the cleavage of lactose into galactose and glucose, which are metabolized via the glycolytic pathway. LacY is selective for disaccharides containing a D-galactopyranosyl ring, as well as D-galactose, but has no affinity for D-glucopyranosides or D-glucose. The K_m of transport is dramatically decreased in the presence of $\Delta\mu_{H^+}$, although the K_D remains unchanged.

By regulation of both transcription of *lacY*, as well as LacY activity by IIA^{Glc} of the PTS, *E. coli* grown in the presence of a mixture of glucose and lactose will utilize the lactose only when the glucose in the medium is completely exhausted, leading to diauxic or biphasic growth.

MelB

MelB of *E. coli*, encoded by the *melB* gene, consists of 473 amino acid residues and is a well-studied member of the glycoside–pentoside–hexuronide:cation symporter family. MelB, containing 12-transmembrane domains, is suggested to share a similar overall fold with LacY (Figure 1). MelB catalyzes the accumulation of galactopyranosides by utilizing the free energy from the energetically downhill inward movement of Na^+ , Li^+ , or H^+ to drive the stoichiometric accumulation of sugar. α -Galactopyranosides (melibiose, raffinose, and *p*-nitrophenyl- α -galactoside) are co-transported with Na^+ , H^+ , or Li^+ , while the β -galactopyranosides (lactose, methyl-1- β -D-galactopyranoside, or *p*-nitrophenyl- β -galactoside) are co-transported with Na^+ or Li^+ but not H^+ . Intracellular α -galactosidase catalyzes the cleavage of melibiose into galactose and glucose, which are metabolized via the glycolytic pathway. Expression and function of MelB are also regulated by the PTS.

SglT

SglT of *V. parahaemolyticus*, encoded by the *sglS* gene, consisting of 543 amino acid residues, has 14-transmembrane helices with extracellular N and C termini. The bacterial SglT catalyzes Na^+ -dependent sugar transport, with sugar preferences

(galactose > glucose > fucose). The structural core is formed from two five-helix inverted repeats, helices II–IV and VII–XI. Different from the MFS, the co-substrate binding sites in the SglT are located in two connected pockets in the middle of the molecule (Figure 2). Expression and function of SglT is not regulated by PTS. Human homologs of SglT are expressed primarily in the epithelia of the small intestine and the kidney where they play important roles in the physiology of these organs.

Binding Protein-Dependent ATP-Binding Cassette Transport System

Classification

Although ABC transporters are broadly distributed in archaea, prokaryotes, and eukaryotes, ABC transport systems that require binding proteins for function are found only in archaea and prokaryotes. All members share the common feature that turnover involves the utilization of energy released from the hydrolysis of ATP to translocate solute in one direction across the membrane against concentration gradient.

Assembly and Structural Features

The binding protein-dependent ABC transporters have a common global organization: two transmembrane domains or subunits, two cytoplasmic nucleotide-binding domains or subunits, also called ATP-binding cassettes, and one substrate-binding protein (Figure 3). Both the integral membrane protein and the cytoplasmic ATP-binding protein may be present as homodimers or heterodimers. Both ABCs are required for transport activity, and the sequences are highly conserved among different ABC transporters. In Gram-negative bacteria, each member of this family possesses a periplasmic binding protein, and in Gram-positive bacteria, the substrate-binding protein is a membrane-bound lipoprotein. Although these binding proteins have diverse specificities, the X-ray structures of the sugar-binding proteins exhibit a similar bilobate architecture composed of two symmetrical lobes surrounding substrate-

Figure 2 Crystal structures of LacY of *E. coli* and SglT of *V. parahaemolyticus*. (a) The X-ray crystal structure of the C154G LacY mutant (1pv7) viewed parallel to the membrane with a bound sugar (green sticks) at the bottom of the large cytoplasmic cavity formed by N- and C-terminal pseudo-symmetric domains. As shown the protein catalyzes the stoichiometric translocation of sugar and H^+ in either direction across the membrane. (b) The X-ray crystal structure of the SglT (3dh4) viewed parallel to the membrane with a bound galactose molecule (green sticks) in the middle of protein.

Figure 3 The X-ray crystal structure of MalEFGK₂ complex (2r6g) of *E. coli* with a bound maltose (green sticks) on MalF and two ATP (red sticks) on MalK. The periplasmic binding protein MalE tightly docks to the membrane proteins MalF and MalG, delivering maltose and stimulating ATPase activity of the cytoplasmic protein MalK. The energy released from the hydrolysis of ATP drives the translocation of maltose across the membrane. The sugar enters the cells in an unchanged form.

binding site. The X-ray crystal structure of the maltodextrin/maltose transport complex of *E. coli* (MalEFGK₂) represents a typical assembly and architecture for this class of transport systems (Figure 3). The two MalK subunits with the ATP-binding cassettes form a closed dimer at the cytoplasmic side, with two ATP molecules bound at the interface. The MalF and MalG subunits with the transmembrane domains consist of 8- and 6-transmembrane helices, respectively, and form a large water-filled central cavity open to the periplasmic side and closed on the cytoplasmic side. A maltose molecule is bound at the bottom of the cavity about half way into the cytoplasmic membrane. The periplasmic MalE subunit or maltose-binding protein (MBP) docks onto MalF and MalG in a sugar-free open conformation and serves as a cap to ensure unidirectional translocation of the sugar. These five subunits assemble into a tight complex through extensive interactions among each subunit.

Functional Properties

The binding protein selectively binds the substrate with high affinity and delivers it to the cavity formed by the cognate MalF and MalG subunits. Interaction of the sugar-bound periplasmic binding protein with MalF and MalG stimulates the ATPase activity of the cytoplasmic ATP-binding domains and initiates the transport process. The sugar enters the cell in an unchanged form. This system has the capacity to accumulate sugars to extremely high levels, and translocation is unidirectional.

Maltodextrin/Maltose Transport

Maltodextrin/maltose transport MalEFGK₂ (Figure 3), encoded by the maltose operon of *E. coli*, is one of the most extensively studied representatives of the binding protein-dependent sugar

transporters. MalE, which is the primary determinant of substrate specificity, recognizes and binds maltodextrin/maltose with high affinity. Sugar-bound MalE docks on the top of the large hydrophilic cavity formed by MalF and MalG complex, allowing direct delivery of the cargo sugar into the central cavity and triggers ATPase activity in MalK. There is a single maltose-binding site on MalF at the bottom of the cavity, which is closed at the cytoplasmic side by tight contact between MalF and MalG, and represents an outward-facing conformation. An alternating access model is also suggested for transport by the MalEFGK₂ complex. In addition, the C-terminal fragment of MalK forms a regulatory domain for EIIA^{Glc} regulation (Figure 1).

Glossary

Insulin resistance A state in which the same concentration of insulin elicits a decreased biological response compared to normal conditions.

Isoform A protein with similar amino acid sequence and same function.

Splice variant Different messenger RNA sequences that originate from the same gene.

Sodium-Dependent Glucose Transporters

The Na⁺/glucose cotransporters are responsible for the absorption of glucose against its concentration gradient by utilizing the energy generated by the electrochemical Na⁺ gradient (Figure 1(a)). These transporters are primarily located in the brush border (apical) membranes of intestinal and kidney epithelial cells and are responsible for the absorption of glucose from the lumen of the small intestine and proximal tubule of the kidney. In the intestines, this transporter functions in the absorption of dietary glucose from the lumen and is then transported across the basolateral membrane into the circulation by the facilitative glucose transporters. Similarly, in the kidneys glucose is filtered into the lumen of the proximal tubule and is reabsorbed by the Na⁺/glucose cotransporters such that under normal physiological conditions, urine is completely depleted of glucose. However, in states of insulin resistance and diabetes, the concentration of luminal glucose may reach such high levels that it exceeds the capacity of the Na⁺/glucose cotransporters to fully reabsorb the filtered glucose.

There are three different isoforms of sodium/glucose cotransporters, namely SGLT1, SGLT2, and SGLT3. Amino acid sequence alignments show that SGLT3 and SGLT2 have identities of 70% and 59% to SGLT1, respectively. The secondary structure model predicted for SGLT1 contains 14 transmembrane α -helices (TMHs) with both the hydrophobic NH₂ terminus and the COOH terminus of TMH 14 facing the extracellular space (Figure 2(a)). All SGLTs probably use the consensus N-linked glycosylation site (N248) between TMH 6 and 7. The predicted molecular weight of these transporters is 73 kDa with the proteins having 659–672 amino acids. The major differences in function between SGLT1 and SGLT2/SGLT3 resides in the selectivity for sugar transport. SGLT1 accepts the natural sugars – glucose and galactose – with comparable affinities and a variety of synthetic sugars such as 3-O-methyl-glucose. SGLT2 and SGLT3 are much more restrictive in that they prefer glucose to galactose or 3-O-methyl-glucose. The affinity of SGLT1 for glucose is 10-fold higher than that of SGLT2 or SGLT3.

Facilitative Glucose Transporters

The facilitative glucose transporters comprise a relatively large family of structurally related proteins that are encoded by distinct genes and are expressed in an overlapping yet tissue-specific manner (Table 1). All the facilitative glucose

transporters are predicted to have 12-membrane-spanning domains and allow for the stereospecific transport of glucose through the lipid bilayer. In contrast to the SGLT1 family, the GLUT4 family has both the NH₂ terminus and the COOH terminus facing the intracellular space. The transport of glucose is energy independent and is solely driven by the relative glucose concentration across the plasma membrane (Figure 1(b)). As under most conditions, the cytoplasmic glucose is rapidly phosphorylated by hexokinase or glucokinase, the relative levels of intracellular glucose are compared to the extracellular concentration resulting in net inward flux of glucose. However, in some instances, glucose can be secreted into the circulation under normal physiological conditions. For example, in hepatocytes facilitative glucose transporters participate in the uptake of glucose from the portal circulation following a meal and in the release of glucose generated by glycogenolysis or gluconeogenesis in the postabsorptive state and during fasting.

Currently, there are 14 identified facilitative hexose transporters in mammalian cells, which have been subdivided into three classes according to the similarity of their amino acid sequences: class I comprises GLUT1, GLUT2, GLUT3, GLUT4, and GLUT14; class II comprises GLUT5, GLUT7, GLUT9, and GLUT12; and class III comprises GLUT6, GLUT8, GLUT10, GLUT12, and the H⁺/myo-inositol transporter (previously termed GLUT13). Each of these transporters exhibit different transport properties and have distinct but overlapping tissue distributions, which underscores their specific physiologic function. For example, GLUT1 is generally expressed and is thought to be responsible for the basal uptake of glucose. GLUT2 is predominantly expressed in the liver and pancreatic β -cells where it functions as part of a sensor-mediating hepatic glucose output during states of fasting and insulin secretion in the postprandial absorption state. In contrast, neurons primarily express the relatively high-affinity GLUT3 isoform necessary to maintain high rates of glucose metabolism for energy production. GLUT8 appears to provide important function during early embryogenesis, whereas GLUT4 is exclusively expressed in insulin-responsive tissues, adipose, and striated muscle. These latter tissues provide the key functional elements responsible for the insulin stimulation of glucose uptake and are key targets for dysregulation in states of insulin resistance and diabetes. The latest GLUT member identified, GLUT14, is present in the testis and seems to have evolved from a gene duplication of GLUT3.

Figure 1 Schematic representation of the glucose transport process mediated by sodium-dependent glucose transporters (a) and facilitative glucose transporters (b).

Figure 2 Schematic representation of the predicted structure of glucose transporters: (a) SGLT-1 and (b) GLUT-1.

GLUT1

GLUT1 was originally identified as the erythrocyte-type facilitative glucose transporter and was the first isoform to be purified and eventually cloned. The amino acid sequence of GLUT1 is highly conserved among different species (i.e., 98% identity between human and rat). Computer analysis of the primary sequence of GLUT1 has revealed that GLUT1 is a hydrophobic protein, with 50% located within the lipid bilayer. Several lines of evidence have supported a structural model for GLUT1 that consists of 12-membrane-spanning α -helical segments and an intracellular located NH_2 and COOH termini. According to this model, a large intracellular segment of 33 amino acids connects transmembrane domains M1 and M2, and an extremely hydrophilic intracellular segment of 65 amino acids joins M6 and M7. Short regions of 7–14 amino acids connect the remaining membrane-spanning regions. There are two potential N-linked glycosylation sites in GLUT1 at Asn-45 and Asn-411, but only the former site in the large extracellular loop has been shown to be glycosylated (**Figure 2(b)**). Although other models have been proposed, structural analysis of GLUT1 topography has confirmed the originally proposed 12-transmembrane-spanning model. The other members of the glucose transporter family are similar in size (between 492 and 524 amino acids) and all are predicted to maintain the 12-transmembrane-spanning structure, although the sites of glycosylation and length of the different intracellular and extracellular loops appear to vary, classes I and II are glycosylated in loop 1, whereas class III is glycosylated in loop 9. The N-glycosylation appears to be required to maintain high-affinity transport for glucose.

GLUT1 is highly expressed in placenta, brain, epithelial cells of the mammary gland, transformed cells, and fetal tissues. Because of its ubiquitous expression it has been proposed that GLUT1 might be responsible, at least in part, for basal glucose uptake. Kinetic studies in erythrocytes have demonstrated that GLUT1 has a K_m of 2 mM for α -glucose, whereas the K_m is greater than 3 M for β -glucose. In addition, it has been postulated that GLUT1 functions in either a dimeric or a tetrameric oligomeric state. This appears to account for the various kinetic properties of glucose transport and, in addition to expression levels and

Table 1 Mammalian facilitative sugar transporters

<i>Isoform</i>	<i>Tissue distribution</i>	<i>Function</i>
GLUT-1	Brain, endothelial cells, placenta, erythrocyte, mammalian gland	Basal transport, transport in fetal tissues
GLUT-2	Liver, small intestine, pancreatic cells, kidney	Basolateral transport in epithelial cells, glucose release from liver
GLUT-3	Neurons, sperm, white blood cells, placenta	Basal transport
GLUT-4	Muscle, heart, white and brown adipose tissue	Insulin-stimulated glucose transport
GLUT-5	Small intestine, kidney, testis, sperm	Fructose transporter
GLUT-6	Spleen, leukocytes, brain	Unknown
GLUT-7	Intestine, prostate	Unknown
GLUT-8	Testis, blastocyst, brain	Unknown
GLUT-9	GLUT9a: liver, kidney, placenta GLUT9b: kidney, placenta	Hexose and urate transporter
GLUT-10	Liver, pancreas	Unknown
GLUT-11	Heart, muscle	Unknown
GLUT-12	Heart, prostate	Unknown
GLUT-13	Brain	H^+ /myo-inositol transporter
GLUT-14	Testis	Unknown

localization, provides another level of control of transporter function. Homozygous deletion of the Glut1 in mice results in embryonic lethality.

GLUT2

The low-affinity GLUT2 facilitative glucose transporter functions in the β -cells of the pancreas to transport glucose in direct proportion to the circulating glucose concentration. This transporter functions in concert with glucokinase such that small increases in glucose influx can signal changes in the adenosine triphosphate/adenosine diphosphate (ATP/ADP) ratio, resulting in a highly sensitive mechanism regulating insulin secretion. The central importance of GLUT2 in the regulation of pancreatic insulin secretion was established with the identification of a patient expressing a defective GLUT2 mutation. This transporter also functions in the liver to allow for shuttling of increased glucose load into glycogen. GLUT2 also appears to play a significant role in the reabsorption of filtered glucose in the kidney and in the basolateral transport of glucose from the digestive tract epithelium into the circulation.

GLUT3

GLUT3 was originally isolated from a fetal skeletal muscle library, but is not significantly expressed in adult muscle. This isoform is primarily expressed in neurons, where it is located in cell processes (axons and dendrites), and it has also been detected in the placenta, endothelial cells, human skeletal muscle, and chondrocytes; and in murine sperm, where it is concentrated in the plasma membrane of the flagellum. GLUT3 has also been found in blastocysts, and is essential for embryonic development and survival. Deletion of GLUT3 in the mouse results in increased apoptosis of blastocysts and loss at embryonic day 8.5. GLUT3 has been detected in white blood cells, in human lymphocytes, monocytes/macrophages, neutrophils, and platelets. Interestingly, GLUT3 appears to have an intracellular localization in these cells, and it is recruited to the cell surface upon cell activation.

GLUT4

In 1989, five research groups independently cloned the insulin-responsive glucose transporter isoform GLUT4. This isoform is predominantly expressed in striated muscle (skeletal and cardiac) and adipose tissue (white and brown), the major tissues that display insulin-stimulated glucose uptake. Sequence analysis of GLUT4 suggests that its secondary structure and orientation in the plasma membrane is similar to GLUT1 with an overall 65% amino acid identity.

In contrast to the other glucose transporters under basal conditions, GLUT4 is predominantly intracellular localized. The primary mechanism responsible for the increase in glucose uptake in insulin-sensitive tissues upon insulin treatment is the recruitment or translocation of glucose transporters from these intracellular storage sites to the plasma membrane. Although the molecular mechanisms that regulate GLUT4 translocation are poorly understood, the trafficking of the GLUT4 protein has several similarities with the trafficking, docking, and fusion of synaptic vesicles in neurons responsible for neurotransmitter release.

The long-term expression of the GLUT4 gene is also controlled during development and during various hormonal, nutritional, and metabolic states. For example, fetal tissues contain very little GLUT4 and expression of this transporter increases after birth. In addition, during states of insulin deficiency such as fasting and following destruction of the insulin secreting β -cells by streptozotocin (STZ)-induced diabetes, GLUT4 expression levels are severely reduced in adipose, heart, and skeletal muscle. Similarly, obesity, high-fat feeding, and muscle denervation also result in a decrease in GLUT4 expression and subsequent insulin resistance. By contrast, GLUT4 is upregulated by exercise training, thyroid hormone treatment, and insulin therapy – treatments that increase insulin sensitivity.

GLUT5

The GLUT5 fructose transporter is highly conserved among species with a 69–88% amino acid identity between mice, human, rat, and rabbit. In mice, expression is highest in small intestine, kidney (proximal tubule), and testis. In humans, it is also present in skeletal muscle and in small amounts in adipocytes. Expression of GLUT5 in adipocytes increases under conditions of hypoxia and obesity. Studies in rats and rabbits have shown that the expression of this transporter is highest in the upper part of the small intestine (duodenum and proximal jejunum). Expression of GLUT5 in the intestine is highly regulated, showing circadian rhythm, dependence on dietary fat and carbohydrate content, and insulin levels. Interestingly, fructose does not regulate GLUT5 expression in adipose cells. GLUT5 has been found in the sperm of numerous species, although its role in sperm metabolism remains obscure.

GLUT6

The GLUT6 gene encodes a complementary DNA (cDNA), which exhibits significant sequence similarity with the other members of the glucose transporter family, particularly GLUT8. GLUT6 protein has been detected in spleen, peripheral leukocytes, and brain. When heterologously expressed in 3T3L1 adipocyte cells this transporter is intracellular localized, but unlike GLUT4 does not translocate to the plasma membrane in response to insulin.

GLUT7

The GLUT gene encodes for a protein of 512 amino acids, which has a sequence identity of 58% with GLUT5. When expressed in *Xenopus* oocytes, this protein transported both glucose and fructose at much lower concentrations than those found for GLUT5. The messenger (mRNA) for GLUT7 (but not yet the protein) has been detected mainly in the small intestine and colon, and to lesser amounts in prostate and testis. The role of GLUT7 in these tissues remains to be elucidated.

GLUT8

GLUT8, previously termed as GLUTX1, is a newly characterized glucose transporter isoform that is expressed at high levels in the testis and the brain, and at lower levels in several other

tissues including spleen, liver, skeletal muscle, heart, and adipose tissue. In the brain, GLUT8 is expressed in the neuronal cell bodies of excitatory and inhibitory neurons in the rat hippocampus. It was found in hippocampal and dentate gyrus neurons as well as in amygdala and primary olfactory cortex. In these neurons, its location was close to the plasma membrane of cell bodies and sometimes in proximal dendrites. High GLUT8 levels were detected in the hypothalamus, supraoptic nucleus, median eminence, and the posterior pituitary. In the testis, it is found in differentiating spermatocytes of type 1 stage and in the acrosomal region it is found in mature spermatozoa. When expressed in *Xenopus* oocytes it exhibits high-affinity transport activity for glucose, which is specifically inhibited by fructose and galactose, suggesting that it may be a multifunctional transporter.

GLUT8 contains a dileucine intracellular localization motif; however, its precise subcellular distribution has been controversial. In some cells, it has been found to be associated with the endoplasmic reticulum, whereas in others it has been detected in late endosomal fractions suggesting that GLUT8 may have a role in the transportation of sugars obtained from lysosomal degradation of glycoproteins. GLUT8-deficient mice display normal growth but with subtle modifications of behavioral traits, and reduced sperm mobility.

GLUT9

GLUT9 has a high-sequence similarity to the fructose transporter GLUT5 and is mainly expressed in the kidney (both proximal and convoluted tubule), liver, and placenta. It has two splice variants GLUT9a and GLUT9b, which differ in the NH₂ terminal part of the molecule and subcellular distribution. GLUT9a is present in the basolateral membrane of epithelial cells whereas GLUT9b is located in the apical membrane. Expression of GLUT9 is regulated by starvation and hyperglycemia. The substrate specificity of this transporter is unique in that it transports hexoses (both glucose and fructose) and uric acid. Since GLUT9 has been found to be present in articular cartilage, it is possible that this transporter may play a role in gout disease.

GLUT10–14

Other than sequence analysis and tissue distribution of mRNA expression, little information is available about the function and properties of GLUT10–14. GLUT10 is primarily expressed in human heart, lung, brain, liver, skeletal muscle, pancreas, placenta, and kidney. GLUT11 gene in humans has three splice variants: GLUT11a is most abundant in skeletal muscle and

heart, although it is also present in kidney; GLUT11b is present in placenta, adipose tissue, and kidney; and GLUT11c is present in adipose tissue, heart skeletal muscle, and pancreas. All GLUT11 isoforms transport glucose and fructose. Interestingly, the GLUT11 gene has not been found in the mouse or rat genome. GLUT12 is expressed in heart, prostate, and has also been detected in breast cancer cells and in epithelial cells of rat mammary gland during pregnancy and lactation. It has dileucine motifs in both NH₂- and COOH-terminal parts of the molecule. In humans, GLUT12 expression is restricted to insulin-sensitive tissues: skeletal muscle, heart, and adipose; and it has been postulated to be another insulin-responsive glucose transporter. GLUT13 is predominantly expressed in the brain and displays an H⁺/myo-inositol transporter activity. It does not transport glucose. GLUT14 is expressed in the testis and is 95% identical to GLUT3.

Glossary

Allosteric site Small-molecule-binding site that is topographically distinct from the endogenous ligand (orthosteric) binding site.

Gamma-aminobutyric acid (GABA) An amino acid that serves as the primary inhibitory neurotransmitter in the central nervous system.

Glutamate An amino acid that serves metabolic functions and as a component of proteins and polypeptides in all cells. In addition, glutamate serves as a major excitatory neurotransmitter in the central nervous system.

G protein Membrane-associated protein that interacts with a particular class of cell-surface receptors and participates in

receptor-induced activation of intracellular enzymes, ion channels, and other signaling molecules. It is also known as guanosine triphosphate (GTP)-binding protein.

Negative allosteric modulator Compound that inhibits the binding and/or activity of an orthosteric ligand via interaction with an allosteric site.

Orthosteric site The binding pocket on a protein to which the endogenous neurotransmitter/hormone binds to activate the receptor.

Positive allosteric modulator Compound that enhances the binding and/or activity of an orthosteric ligand by binding to an allosteric site.

Fast Synaptic Transmission and Neuromodulation in the Central Nervous System

The majority of connections that make up a neural network in the mammalian central nervous system are synaptic connections in which a neurotransmitter released from the presynaptic neuron activates postsynaptic receptors that are neurotransmitter-gated ion channels. Opening of these ion channels results in either excitation or inhibition of a receptive neuron; these processes are, respectively, known as fast excitatory and inhibitory synaptic transmission. Normal function of the central nervous system (CNS) requires a delicate balance between excitatory and inhibitory transmission. In mammalian brain, two major neurotransmitters are responsible for most fast inhibitory and excitatory synaptic responses. Gamma-aminobutyric acid (GABA) is the principal inhibitory neurotransmitter, whereas the amino acid glutamate is the primary excitatory neurotransmitter. Transmission through a neuronal circuit can be fine-tuned or regulated by activation of another class of receptor that couples to activation of second-messenger systems and various biochemical processes through guanosine triphosphate (GTP)-binding proteins (G proteins). This form of synaptic transmission is often referred to as slow synaptic transmission or neuromodulation to differentiate it from fast excitatory and inhibitory transmission.

Fast Excitatory and Neuromodulatory Actions of Glutamate

As the primary fast excitatory neurotransmitter, glutamate plays an important role in virtually all major functions of the CNS. Traditionally, the actions of glutamate were thought to be mediated exclusively by activation of glutamate-gated cation channels termed ionotropic-glutamate (iGlu) receptors.

Fine-tuning or modulation of transmission through glutamatergic circuits was thought to require neuromodulators from extrinsic afferents such as dopamine, acetylcholine, serotonin, and norepinephrine that activate G protein-coupled receptors (GPCRs). However, in the mid-1980s, evidence for the existence of glutamate receptors directly coupled to second-messenger systems through G proteins began to appear with the discovery of glutamate receptors coupled to activation of phosphoinositide hydrolysis. A key turning point being the discovery of *trans*-1-amino-1,3-cyclopentanedicarboxylate that activated glutamate receptors coupled to phosphoinositide hydrolysis while having no effect on iGlu receptors. Since that time, it has become clear that glutamate activates a large family of receptors, termed metabotropic glutamate (mGlu) receptors, which signal by coupling to G proteins.

The discovery of mGlu receptors dramatically altered the traditional view of glutamatergic neurotransmission because activation of mGlu receptors can modulate activity in glutamatergic circuits in a manner previously associated only with neuromodulators from non-glutamatergic afferents. However, unlike receptors for monoamines and other neuromodulators, the mGlu receptors provide a mechanism by which glutamate can modulate or fine-tune activity at the same synapses at which it elicits fast synaptic responses. Because of the ubiquitous distribution of glutamatergic synapses, mGlu receptors participate in a wide variety of functions of the CNS.

Eight mGlu Receptor Subtypes

A major breakthrough in the understanding of mGlu receptors occurred in 1991 when groups led by Shigetada Nakanishi at Kyoto University in Japan and by Eileen Mulvihill and F.S. Hagen at ZymoGenetics, Inc., in Seattle, Washington, independently cloned the first gene encoding an mGlu receptor.

A search for related complementary DNA (cDNA) resulted in the isolation of seven other genes encoding different mGlu receptor subtypes, named mGlu1 through mGlu8. Also, with the exception of mGlu2, several alternatively spliced forms or structural variants have been isolated for the mGlu receptor subtypes. These include splice variants for mGlu1 (a–d), mGlu3 (GRM3Δ2, GRM3Δ4, GRM3Δ2Δ3, and GRM3Δ4) mGlu4 (a and b), mGlu5 (a and b), mGlu6 (a–c), mGlu7 (a–e), and mGlu8 (a–c). Thus, it is now clear that there is tremendous diversity within the mGlu receptor family.

The mGlu receptors belong to family C GPCRs, which also include GABA_B receptors, calcium-sensing receptors, pheromone receptors, and taste receptors. Although the predicted topology of these receptors is similar to rhodopsin receptors and other GPCRs in that they contain seven predicted transmembrane-spanning domains, the primary structure of this family shares very little sequence homology with other GPCRs. With the exception of orphan receptors, all family C GPCRs are characterized by a large extracellular N-terminus, referred to as the Venus flytrap (VFT) domain, which contains the endogenous ligand-binding site. Numerous structure–function studies suggest that the VFT domain of mGlu receptors is made up of two globular domains with a hinge region. This forms a clam-shell-shaped structure, with the glutamate-binding site residing between the two globular domains (see Figure 1). Evidence suggests that when glutamate binds, the globular domains close into a stable conformation with glutamate inside. The conformation changes induced by glutamate binding are transmitted via the cysteine-rich domain (CRD) to the transmembrane-spanning α -helices, subsequently promoting coupling to intracellular G proteins and activation of second-messenger pathways. The CRD contains nine cysteine residues and X-ray crystallographic studies have shown that eight of these form disulfide bonds within this region, while

the ninth forms a disulfide bond with a cysteine in the VFT. The transmembrane-spanning α -helical domains contain small-molecule-binding sites (allosteric sites) that depending upon the ligand can either inhibit (negative allosteric modulators) or enhance (positive allosteric modulators) the function of the receptor, while the intracellular loops and large C terminal domain of the mGlu receptors are important determinants for G protein-coupling specificity as well as regions subject to alternate splicing and regulation by phosphorylation and protein–protein interactions.

The cloned mGlu receptors have been classified into three major groups based on sequence homology, pharmacological properties, and coupling to different second-messenger pathways. Group I includes mGlu1 and mGlu5, group II, mGlu2 and mGlu3, and group III, all the others. mGlu receptors of the same group show ~70% sequence identity, whereas between groups this percentage falls to ~45% (Figure 2). Group I mGlu receptors preferentially couple to activation of the G_{q/11} family of G proteins activating phosphoinositide hydrolysis as the major signaling mechanism. By contrast, group II and group III mGlu receptors preferentially couple to G_{i/o} and inhibition of adenylyl cyclases. Members of each group have a unique pharmacological profile and can be selectively activated by specific agonists that have no effects on members of the other groups of mGlu receptors. Also, in recent years, progress has been made in developing ligands, predominantly allosteric modulators, which differentiate between members of a single group. These ligands are having a major impact on the understanding of the physiological roles and pharmacological properties of the different mGlu receptor subtypes.

mGlu Receptors Play Diverse Roles in Regulating Neuronal Excitability and Synaptic Transmission

With the exception of mGlu6, which is localized to the retina, mGlu receptors are ubiquitously expressed throughout the

Figure 1 Schematic representation of an mGlu receptor. The mGlu receptors contain a large extracellular N-terminal domain, seven-transmembrane-spanning regions, and an intracellular C-terminal domain. Glutamate binds in the large extracellular domain. CNS. Anatomical studies using probes that specifically interact with individual subtypes coupled with electrophysiological studies have revealed that each mGlu receptor subtype is differentially localized in different brain regions. In recent years, all mGlu receptor subtypes have been genetically deleted in mice; studies using these animals have yielded further insights into the biological functions of mGlu receptors as well as potential diseases where mGlu receptors may be a viable target for therapeutic intervention. Although it is clear that the specific mGlu receptor subtype involved in mediating a given effect varies in different brain regions, some generalizations can be made regarding the major roles of different groups of mGlu receptors. Elucidation of these roles of mGlu receptors suggests that selective agonists and antagonists of specific mGlu receptor subtypes could subtly alter transmission in glutamatergic circuits in a way that would provide a therapeutic benefit without eliciting the side effects commonly associated with drugs that interact with members of the iGlu receptor family.

One of the most common physiological functions of mGlu receptors seen throughout the CNS is as autoreceptors present at presynaptic terminals at glutamatergic synapses. Activation of these presynaptic receptors results in a reduction of glutamate release at that synapse. It is likely that this provides a negative feedback mechanism for tightly controlling transmission at glutamatergic synapses. This presynaptic function of mGlu receptors is usually served by a group II mGlu receptor or by one of the group III mGlu receptors. Although multiple mGlu receptor subtypes can serve this role, the specific mGlu receptor subtype(s) involved varies from synapse to synapse. mGlu receptors also exist postsynaptically where they play an important role in regulating cell excitability. The most common postsynaptic effect of mGlu receptor activation is induction of an increase in neuronal excitability. Again, the specific mGlu receptor subtype involved varies from synapse to synapse but typically involves one of the group I mGlu receptors. In some cells, activation of postsynaptic mGlu receptors can lead to hyperpolarization and a reduction in neuronal excitability. This has been observed for both group I and group II mGlu receptors. Finally, a commonly observed effect of mGlu receptor activation is regulation of transmission at inhibitory (GABAergic) and neuromodulatory (acetylcholine, monoamines, and peptides) synapses. In this case, group II and III mGlu receptors are often found localized at presynaptic terminals or preterminal axons where they regulate neurotransmitter release. In addition to these effects on neuronal function, mGlu receptors can also exist on glial cells, the most prominent being mGlu3 and mGlu5. Although mGlu receptors can have a number of effects on glial function, Ferdinando Nicoletti and co-workers have reported a series of studies revealing that one important effect of mGlu receptors in glia is the induction of release of neuroprotective factors that reduce excitotoxicity and protect neurons from damage.

Therapeutic Potential of mGlu Receptor Ligands

Given the wide diversity, heterogeneous distribution, and diverse physiological roles of mGlu receptor subtypes, the opportunity exists for developing therapeutic agents that selectively interact with mGlu receptors involved in only one or a

limited number of CNS functions. A potential advantage of developing new therapeutic agents that specifically target mGlu receptors is that it provides a rational approach for subtle fine-tuning of activity at glutamatergic synapses in the circuits implicated in a particular disease. Because of this, a great deal of effort has been focused on developing small molecules that selectively activate or inhibit specific mGlu receptor subtypes. One of the most important and earliest breakthroughs in developing drugs that target mGlu receptors was the development of highly selective agonists for the group II mGlu receptors by Jim Monn, Darryle Schoepp, and their co-workers at Eli Lilly. Indeed, preclinical studies revealed robust anxiolytic and antipsychotic effects of these agonists, and subsequent clinical studies have shown that selective group II agonists have efficacy in the treatment of anxiety, panic attacks, and schizophrenia.

Preclinical studies of compounds selective for other mGlu receptor subtypes have also shown much promise for drug development. Hyperactivity of glutamatergic neurotransmission is thought to underlie a number of different CNS disorders and, in certain brain regions, mGlu5 activation induces the activity of the *N*-methyl-D-aspartate (NMDA) subtype of iGlu receptors. Thus, inhibition of mGlu5 function by selective negative allosteric modulators is an attractive avenue for therapeutic development for fragile X syndrome, anxiety disorders, chronic pain, addiction, depression, migraine, and gastroesophageal reflux disorder. Conversely, hypofunction of glutamatergic synapses has been implicated in the pathophysiology of schizophrenia and cognitive disorders, such that activation of positive allosteric modulators that enhance mGlu5 activity resulting in the potentiation of NMDA currents is a promising novel approach for therapeutic intervention. Another potential target is mGlu4, as activation of mGlu4 reduces GABAergic transmission at synapses that have been implicated in the pathology of Parkinson's disease. Indeed, selective enhancement of mGlu4 activity by positive allosteric modulators has been shown to have anti-parkinsonian effects in preclinical animal models. Over the past decade, our understanding of mGlu receptor biology has grown considerably, with the discovery of compounds that selectively activate/inhibit individual mGlu subtypes, providing many insights into the biological functions and pathologies associated with these receptors.

Glutathione Peroxidases

F Ursini and M Maiorino, University of Padua, Padua, Italy

© 2013 Elsevier Inc. All rights reserved.

Glossary

Antioxidant A molecule or an enzymatic system capable of slowing or preventing the oxidation of other molecules. Oxidation is a chemical reaction that transfers electrons from a substance to an oxidizing agent. Oxidation reactions can produce free radicals, which start chain reactions that damage cells. Antioxidants terminate these chain reactions by removing free radical intermediates, and inhibit other oxidation reactions by being oxidized themselves.

Apoptosis The process of programmed cell death that occurs in multicellular organisms. Programmed cell death involves a series of biochemical events leading to change of cell morphology and death.

Glutathione A cysteine-containing tripeptide (γ -glutamyl-cysteinyl-glycine) found in most forms of aerobic life. Glutathione exists in reduced (GSH) and oxidized (GSSG) states. GSH is involved in antioxidant protection and regulation of the redox status of the cells. Here it is usually found almost exclusively in its reduced form, since the enzyme that reverts GSSG in a NADPH-dependent reaction, glutathione reductase, is constitutively active and inducible upon oxidative stress.

Lipid peroxidation The oxidative degradation of lipids. It is the process whereby free radicals steal electrons from the lipids (mainly poly-unsaturated) in cell membranes, resulting in cell damage. This process proceeds by a free radical chain reaction mechanism and produces lipid hydroperoxides and their degradation products.

Mitochondrial capsules A keratinous-like structure containing a large amount of disulfides, wrapping the mitochondria in the mid-piece of mammalian spermatozoa.

Peroxidase An enzyme belonging to the class of oxidoreductases catalyzing the reduction of a hydroperoxide to the corresponding alcohol and water by using the reducing potential of a specific substrate.

Peroxiredoxins A ubiquitous family of peroxidases not homologous to the glutathione peroxidase (GPx) family of

proteins. Peroxiredoxins use Cys catalysis and thioredoxins or other redoxins as donor substrate for hydroperoxide reduction. Prxs are divided into three classes: typical 2-Cys Prxs, atypical 2-Cys Prxs, and 1-Cys Prxs. The atypical 2-Cys Prxs use the same mechanism as typical 2-Cys Prxs but, differently to these, are functionally monomeric proteins. In atypical 2-Cys Prxs, both the peroxidatic Cys and its corresponding resolving Cys are contained within the same polypeptide, with the condensation reaction resulting in the formation of an intramolecular disulfide bond.

Phosphatidylcholine hydroperoxide A membrane lipid hydroperoxide, which is a nonradical intermediate of membrane lipid peroxidation.

Selenium A chemical element represented by the chemical symbol Se. It is chemically related to sulfur and tellurium. Although toxic in large amount, Se is nutritionally essential in traces for animals, being necessary for the functions of specific selenoenzymes (at least 25 in humans), some of which are essential for life. Selenoenzymes contain Se in the form of selenocysteine (three letter code: Sec, one letter code: U) as the redox active moiety. Sec is inserted in the protein during translation and it is therefore the 21st naturally occurring protein amino acid.

Selenoproteins Proteins that contain at least one selenocysteine residue. Selenocysteine has a structure similar to cysteine, but with an atom of selenium substituting for sulfur.

Sperm mitochondria cysteine-rich protein (SMCP)

A protein that is a structural component of the sperm mitochondrial capsule. It contains unusual motifs made of adjacent Cys residues (CC).

Thiol A compound that contains the functional group composed of a sulfur-hydrogen bond ($-SH$).

Thioredoxins and redoxins Proteins that act as reductants by reducing disulfides by a cysteine thiol-disulfide exchange reaction. They are characterized by the CXXC motif.

They exhibit a typical tertiary structure named the 'thioredoxin fold'.

The term 'glutathione peroxidase' (GPx) describes a family of phylogenetically related proteins. It was coined after GPx-1, the mammalian tetrameric selenoenzyme first described and characterized.

GPx-1 reduces various hydroperoxides by glutathione (GSH):

So far, the GPx family encompasses more than 700 members spread over all domains of life, mostly only known as deduced sequence.

History

In 1957, G. C. Mills described glutathione peroxidase (GPx) activity in red blood cells and showed that it could protect hemoglobin from oxidative breakdown. In 1973, the group of Hoekstra in Wisconsin reported that in a model of rat Se-deficiency reproducing the human pathological condition of favism, GPx activity was low and radioactive selenium coeluted with GPx activity. Almost at the same time, the team of Flohé in Germany showed that the purified enzyme contained one selenium atom per subunit and studied the catalytic mechanism

and the peculiar kinetics. Soon the tetrameric enzyme, today known as GPx-1, emerged as the most efficient H_2O_2 removing system present in the cytosol of almost every mammalian cell.

The selenium moiety of GPx-1 was later identified as selenocysteine (Sec) in the laboratories of Al Tappel (USA) and A. Wendel (Germany), while, few years later, protein sequencing demonstrated that the Sec residue was inserted in the GPx-1 peptide chain as the 21st of the naturally occurring amino acids. The discovery of Se in GPx-1 enforced a revision of the appreciation of selenium as a just toxic, carcinogenic, and teratogenic element.

GPx-1 remained the only glutathione peroxidase known until 1982, when the team of F. Ursini in Italy described a monomeric glutathione peroxidase that, differently from GPx-1, protects membrane peroxidation by reducing phospholipid hydroperoxides. The new enzyme was named 'phospholipid hydroperoxide glutathione peroxidase' (PHGPx). PHGPx was fully acknowledged as a new glutathione peroxidase only in 1991, when primary structure studies showed that it was a new selenoprotein poorly related to GPx-1. Notably, the strongly conserved peptide loops constituting the active site of GPx-1 were retained in PHGPx. PHGPx is known today as GPx-4. In the meanwhile, other GPx homologs were described in mammals.

To date, the list of mammalian GPxs has grown up to eight. Most of them are selenoproteins (SecGPxs) often coexisting in different cell types (GPx-1, GPx-2, GPx-4, and GPx-6, which is indeed mainly expressed in embryo and olfactory epithelium). One of them, GPx-3, is extracellular. In the remaining variants, the active site Sec residue is replaced by Cys (CysGPxs) (GPx-5, GPx-6 in some species, GPx-7, and GPx-8). Only GPx-4, GPx-7, and GPx-8 are monomeric while the others are tetrameric. The alternative use of Cys or Sec as the peroxidatic residue ($\text{C}_\text{P}/\text{U}_\text{P}$) brought into the focus the still challenging question of the biological advantage of having sulfur rather than selenium in these enzymes.

Accumulation of genomic databases allowed the analysis of homologous proteins from diverse taxonomical groups. From these studies it emerges that the SecGPxs are just a minority, only found in mammalian and in nonmammalian vertebrates, in parasitic trematodes, and, sporadically, in protists and bacteria. On the other hand, monomeric CysGPxs are the most abundant type of glutathione peroxidases, found in terrestrial plants, insects, bacteria, fungi, and protozoa. Most of these monomeric homologs contain a nonaligned second Cys residue that represents a second redox center (resolving Cys, C_R) conferring specificity for redoxins as reducing substrate. Therefore, the historical term 'glutathione peroxidase' turns today to be a misnomer that when all domains of life are considered, it functionally describes just a small subgroup of GPxs.

Enzymology and Kinetics

The kinetic mechanism of GPxs has been first worked out for the Sec-containing homologs, GPx-1, GPx-3, and GPx-4. The reaction encompasses two independent events: oxidation of the reduced enzyme by a hydroperoxide (ROOH) and reduction of the oxidized enzyme by GSH (Figure 1).

In the oxidative phase of the catalytic cycle, the selenolate at the active site is oxidized by the hydroperoxide. This first step is

Figure 1 Scheme of the kinetic mechanism of SecGPxs. In the oxidative phase, the reduced enzyme is oxidized to form a putative selenenic acid derivative. For this reaction, the rate constant k_{+1} is identical to that obtained by the kinetic analysis ($k_{+1} = k'_{+1}$). In the reductive phase, the putative selenenic acid derivative of the enzyme is reduced back in two steps by GSH. The product of the first reaction is a glutathionylated intermediate that is resolved by a second molecule of GSH. The rate constant for these two steps, k_{+2} and k_{+3} , cannot be separated by steady-state kinetic analysis. This indeed restitutes the cumulative k'_{+2} value, where $k'_{+2} = k_{+2} + k_{+3}$. For simplicity, the enzyme–substrate complexes are not depicted, and only forward reactions are considered, although enzyme–substrate complexes may be postulated at least in the reducing phase of catalysis and the two reducing steps may be reversible (see text for details).

assumed to occur without formation of a typical enzyme–substrate complex, being the active site selenolate accessible and reactive enough to promptly reduce any hydroperoxide group that comes close. Accordingly, for SecGPxs the apparent rate constant for this step (k_{+1} in Figure 1) is among the fastest ever determined for bimolecular enzymatic reactions (around $10^8 \text{ M}^{-1} \text{ s}^{-1}$). The product is assumed a selenenic acid derivative, although a chemical evidence is missing, due to the extreme reactivity of the group.

The reductive phase is more complex. The overall reduction of the oxidized selenium proceeds by two subsequent steps, the first yielding the glutathionylated enzyme, that is, a selenodisulfide. In the second reduction step, a second GSH molecule forms the stable end product GSSG and releases the reduced selenium for the next cycle.

As in the oxidative step, in the reductive steps the kinetic pattern did not reveal any enzyme–substrate complex. Thus, even if an enzyme–substrate complex maybe invoked for each of the two reductive steps, its decay is not rate limiting. In summary, the kinetics of GPxs is described by a ping-pong mechanism which does not comply with the Michaelis–Menten assumption, where the decay of an enzyme–substrate complex is the rate-limiting step and leads to a saturation kinetics.

The pertinent Dalziel equation that describes this kinetic behavior is the following:

$$[\text{E}_0]/v_0 = 1/k'_{+1} \cdot [\text{ROOH}] + 1/k'_{+2} \cdot [\text{GSH}]$$

where k'_{+1} and k'_{+2} are the apparent rate constants for the net forward oxidative and reductive part of the catalytic cycle, respectively.

Ping-pong kinetics with substrate saturation have been reported for the Cys homolog of *Plasmodium falciparum* and more recently also for other CysGPxs, but not with the GPx

Figure 2 Scheme of the kinetic mechanism of the monomeric CysGPxs carrying the resolving Cys residue. Typically, these proteins mimic the atypical 2-Cys peroxidoredoxin catalysis and use redoxins as substrate for the reductive phase (see text). Here, the reaction with Trx is depicted. S_P's indicate the thiol group of the GPx peroxidatic Cys and S_R's the thiol group of the GPx resolving Cys. See legend of **Figure 1** for details.

from *Drosophila melanogaster*. These are enzymes that, like many other nonmammalian GPxs, mimic the catalysis of atypical 2-Cys peroxidoredoxins in terms of mechanism and specificity (**Figure 2**).

After oxidation of the peroxidatic Cys (C_P), a disulfide bridge is formed with the C_R, which is attacked at the sulfur of C_R by the reducing substrate, which here is Trx or other redoxins. Thus, in GPxs, the switch to saturation kinetic is not necessarily associated with the peroxidoredoxin-like mechanism and therefore the kinetic mechanism may change with species, the substrates involved, or even testing conditions.

Rate constants (i.e., k'_{+1} and k'_{+2} values) calculated from steady-state kinetics for some SecGPxs, for the chimeric cysteine variant of GPx-4 and for some naturally occurring CysGPxs, reveal that while the SecGPxs are more efficient, also the CysGPxs can deal with a physiologically relevant hydroperoxide removal.

In the SecGPx homologs, the reductive part of the catalytic cycle is the rate-limiting step of the overall reaction. In addition, k'_{+2} values decline from GPx-1 to GPx-3 and GPx-4, suggesting that among the SecGPxs, GPx-4 has the lowest reactivity with GSH. The nonmammalian cysteine variants are specifically and efficiently reduced by redoxins and show only marginal activities with GSH.

Substrate Specificity

Glutathione peroxidases are poorly specific in respect to the oxidizing substrates. However, differences do exist and have important biological outcomes. GPx-1 has been shown to reduce a large variety of organic hydroperoxides, although complex lipid hydroperoxides, such as phosphatidylcholine (PCOOH), cholesterol (ChOOH), and cholesterol ester hydroperoxide (CEOOH), are not substrates. In mammals, PCOOH is preferentially reduced by GPx-4 (k'_{+1} values of $10^7 \text{ M}^{-1} \text{ s}^{-1}$ for human and porcine GPx-4 have been measured), which reduces ChOOH and CEOOH as well. Reduction of PCOOH has also been observed for the mammalian extracellular GPx-3, but the rate constant for this reaction is two orders of magnitude lower than that of GPx-4. Furthermore, GPx-3 does not react with CEOOH. Activity with PCOOH is also generally

observed in nonmammalian CysGPxs that, like GPx-4, are monomeric. In mammals, the reduction of complex hydroperoxides is relevant on the light of the anti-apoptotic role of GPx-4 (see below).

Taking into account all life domains, the prevailing reducing substrates in the GPx family are thioredoxins (Trxs) or other redoxins. GSH, instead, is the preferred substrate of the mammalian SecGPxs. GPx-4 reacts 5 times as fast with dithiothreitol than with GSH, almost equally fast with mercaptoethanol and significantly also with cysteine, when none of them is accepted by GPx-1. The ability of GPx-4 to react with a large variety of protein thiols is linked to its function in spermatogenesis (see below). These protein substrates include chromatin, fragments of the sperm mitochondrion-associated cysteine-rich protein (SMCP) where adjacent Cys residues are oxidized.

Structure

Altogether, almost 20 structures of GPx homologs are deposited in the data bank. They display a tertiary structure similar to that first observed for Trx, and shared with many families of oxidoreductases, consisting of a four-stranded β -sheet and three flanking α -helices that yield a two-layer $\alpha/\beta/\alpha$ sandwich with a $\beta_1\alpha_1\beta_2\alpha_2\beta_3\beta_4\alpha_3$ secondary structure pattern. In GPxs the Trx-like fold contains additional stretches of amino acids (**Figure 3**).

Two additional β -sheets are located at the N-terminus, one α -helix and one β -sheet between β_2 and α_2 . Notably, within this additional α -helix lies the C_R in the majority of the Cys homologs and, in the tetrameric homologs only, this stretch of amino acids extends a little further to form an inter-monomer interface. Another additional stretch of amino acids is located between α_2 and β_3 . This participates to the tetrameric interface of GPx-1 and therefore it is deleted in the monomeric homologs. A typical feature of Trx-like fold is a conserved Cys-X-X-Cys active site motif that in the majority of GPx is changed to a Sec/Cys-X-X-Thr (**Figure 4**). This strongly conserved Thr residue appears to be important for structural stability.

The active site pocket of GPxs lies in a flat cleft of the protein surface. The redox active Se, or S, is at hydrogen-bonding distances from three strongly conserved residues, a Gln, a Trp, and an Asn located in distant loops in the primary structure (**Figures 4** and **5**). These residues represent the signature of the entire family and contribute to catalysis.

Considering that the bimolecular rate constants for the oxidation of a fully dissociated Cys by H_2O_2 do not exceed $21 \text{ M}^{-1} \text{ s}^{-1}$, and that theoretical predictions of the unknown rate constants for free Sec oxidations yields similar values, to explain the surprising velocity of the enzymatic reduction of ROOH by GPx, the tetrad of the GPxs catalytic center must play a peculiar role. Tentatively it was assumed that the active site has to fulfill the following requirements: (1) dissociation of the active site (seleno)cysteine to make it as nucleophilic as possible, (2) polarization of the substrate hydroperoxy group, and (3) proton donation for generating an ROH as a good leaving group.

Comparison of the active sites of the two extremes, human GPx1 and human GPx-4, in respect to accessibility and

Figure 3 Topological diagram for Trx fold (left) and GPx fold (right). The additional sheets and helices of the GPx fold are shown in dark. A tiny arrow indicates the position of the selenocysteine residue in SecGPxs. The bold line represents the stretch of amino acids composing the tetrameric interface that is deleted in the monomeric members. In the invertebrate and plant CysGPxs, the C_R residue is located typically in a nonconserved position within the additional α -helix (not shown).

Figure 4 Comparison of some GPx homologs. The sequence of some SecGPxs and CysGPxs – that is, the GPx-1, GPx-2, and GPx-3 from *Homo sapiens* and GPx-7, GPx3, and GPx2 from *Homo sapiens*, *Saccharomyces cerevisiae*, and *Arabidopsis thaliana*, respectively – have been taken as examples. U indicates the selenocysteine residue. The arrows at the bottom indicate the four residues involved in the catalysis. Note the C/UxxT motif typical of GPxs. The arrows at the top indicate the basic residues that, in GPx-1, have been proposed to direct GSH toward the catalytic center. The gray and the black thick lines indicate the dimer interface and the tetramer interfaces, respectively. The thin line indicates the block that typically contains the resolving Cys (C_R) in the invertebrate CysGPx. Note that the amino acids composing the dimer and tetramer interfaces are deleted in the monomeric homologs. See text for details.

electrostatic environment of the peroxidatic Sec residue (U_P), might offer explanation for the peculiar reactivity with PCOOH of GPx-4. First, as in the other monomeric isoforms, the tetrameric interface is deleted. Since this stretch of amino acids partially shields the active site Trp residue in the

tetrameric homologs, it is believed that its absence facilitates accessibility to complex lipid substrates. Consistently, reactivity with PCOOH and other complex lipid substrates is generally a shared feature of the monomeric GPxs. Second, in both human GPx-1 and GPx-4, the selenium protrudes from a flat

Figure 5 Ribbon representation showing the overall structure of the U46C mutant of the human GPx-4. The active site residues, including the peroxidatic residue here mutated into Cys (Cys 46), Gln 81, Trp 142, and Asn 143, are shown as spheres. The yellow sphere represents the sulfur of the Cys replacing the selenocysteine.

area made up by some hydrophobic and basic residues that lend a cationic character to the active site. Besides the positive charges in close proximity to U_p , a second large positively charged area is present in human GPx-4. In the tetrameric congeners, this part is largely covered by a loop that forms the subunit interface. In GPx-4, this second cluster of positive charges is expected to contribute to the binding of exposed polar heads of phospholipids, conferring to GPx-4 the ability to catalyze interfacial reactions.

Within the mammalian SecGPxs, the specificity for the reducing substrate may be explained also on the ground of structural considerations. It has been proposed that in GPx-1 four Arg and one Lys residues provide an electrostatic architecture that directs the donor substrate GSH toward the catalytic center, in a way that its sulfhydryl group contacts the oxidized selenium. In the other GPxs, the peculiar architecture of the GSH binding site is conserved only partially in GPx-2 and GPx-3 and not at all in GPx-4 (Figure 4); therefore, the specificity of GPxs toward GSH should decline in the following order: GPx-1 > GPx-2 > GPx-3 > GPx-4.

Thioredoxin specificity appears to be the domain of CysGPxs that, containing an intramolecular C_R , mimics the atypical 2Cys peroxiredoxin catalysis. Besides C_R , the other peculiar feature of GPxs to determine Trx specificity is deletion of the tetramerization interface, leading to flexibility of the C_R -containing loop. The disulfide bridge in the oxidized enzyme provides the canonical motif for the reduction by a CXXC protein. An intriguing mechanistic variation of the CysGPx homologs is that of the *Saccharomyces cerevisiae* GPx-3, that *in vivo* can oxidize a specific transcription factor, as discussed in the next section.

Biological Functions

Hydroperoxides are unstable compounds produced in cells either enzymatically or as byproducts of oxygen metabolism.

Their homo- or heterolytic decomposition, in many inflammatory diseases, produces reactive species damaging tissues. Therefore, by removing hydroperoxides, GPxs have for long been considered for their antioxidant and anti-inflammatory function.

More recently, it has been recognized that hydroperoxides are also involved in cell growth, differentiation, proliferation, and apoptosis, most likely by interacting with different signaling mechanisms where oxidation-prone cysteines undergo a functional redox switch. Thus, GPxs play a role in these processes by dampening the oxidant signal and/or targeting the oxidative signal to specific protein thiols. An interesting example is that of *S. cerevisiae* GPx-3. In this specie, the Yap1 transcription factor regulates hydroperoxide homeostasis and is activated when hydroperoxide level increases. When oxidized by H_2O_2 , GPx-3 C_{p36} bridges Yap1 Cys598 by a disulfide bond. This intermolecular disulfide bond is then reshuffled into a Yap1 intramolecular disulfide, giving rise to the activated form of the regulator. Thioredoxin turns off the pathway by reducing both sensor and regulator. Thus, yeast GPx3 works as H_2O_2 receptor and redox transducer in gene activation by oxidizing specific thiols of a transcription factor.

The role of mammalian SecGPx as 'effector' of oxidative stress has been only proved for the mitochondrial and nuclear forms of GPx-4. The oxidation of these proteins within spermatozoa results indeed in oxidation of critical thiols relevant to the process of sperm cell maturation (see below).

On the other hand, reverse genetics suggest that GPx-2 and the cytosolic form of GPx-4 may be involved in regulating signaling cascades depending on hydroperoxides, through still not fully defined mechanisms.

What is presently known about the biological functions of mammalian SecGPxs is briefly summarized below.

H_2O_2 metabolism is the domain of GPx-1. This enzyme has been found practically in all investigated tissue, although very low in male germ cells. GPx-1 knockout (k.o) mice model confirms the antioxidant role. These mice are vital, grow and develop normally, but are extremely sensitive to oxidative challenges (i.e., exposure to redox cyclers or induction of oxidative burst in the phagocytic system). Worthy of note is the evidence that the phenotype is not affected by selenium status. This indicates that none of the other SeGPxs, nor any other selenoprotein or peroxiredoxins – indeed functionally depending on the selenoproteins thioredoxin reductases – can compete with GPx-1 in the defense against a generalized oxidative challenge.

Interestingly, over-expression of GPx-1 in mice leads to obesity and insulin resistance, which underscores the role H_2O_2 in the signaling cascade of insulin.

GPx-2, the glutathione peroxidase known as 'gastrointestinal', is mainly expressed in the whole gastrointestinal tract, including the squamous epithelium of the esophagus. In humans, it is also detectable in the liver. The enzyme is part of the battery of genes that are up-regulated by the Nrf2/Keap1 system and it is over-expressed in cancer cells, where this pathway is often activated. Similarly to GPx-1, also GPx-2 k.o mice do not display any significant phenotype in unstressed conditions. The k.o of both these enzymes, however, yields a model of inflammatory bowel disease. Although GPx-2 activity in the gut makes up at best 50% of the total GPx activity, only one allele of GPx-2, but not of GPx-1, is enough to rescue

the phenotype. Clearly, a specific role has to be attributed to GPx-2 that is not substituted by GPx-1. This seems to be somehow related to the control of apoptosis. Indeed, shortened intestinal villi have been observed in GPx-2 k.o mice, suggesting an increased but still tolerated apoptosis rate in these animals. Furthermore, there is less apoptosis in GPx-2 over-expressing MCF7 cells, indicating that GPx-2, by down-regulating apoptosis, promotes cell growth.

GPx-3 is also known as plasma glutathione peroxidase. The GPx-3 transcript contains a signal peptide sequence that is cleaved off in the mature protein. Accordingly, GPx-3 messenger RNA (mRNA) has been found in several tissues and the protein in extracellular compartments such as amniotic fluid, lining fluid of the lung, thyroid lumen, and chamber water of the eye. The major source of plasma GPx-3 is, however, the kidney. GPx-3 is secreted primarily by proximal convoluted tubule cells and binds to the extracellular matrix and to the basement membrane of tubules. It has been proposed that bound GPx-3 is a reservoir of enzyme, mobilized when needed to contrast an oxidative challenge in plasma. However, the role of GPx-3 is not obvious, since reducing equivalents are extremely limited in plasma and extracellular fluids.

GPx-3 k.o mice do not display any significant phenotype, at least under unstressed conditions, also when deletion is associated with deletion of GPx-1.

GPx-4 is an intracellular enzyme expressed at low level almost ubiquitously, with the exception of male germ cells of testis where expression is high, and the glial cells of the brain, where, instead, it is undetectable. Notably, the absence of GPx-4 mRNA has also been reported in the islets of Langerhans, in the adenohypophysis, and in the lymphoid follicles of the white pulp of the spleen.

GPx-4, also known as PHGPx, performs the broadest variety of functions. As mentioned above, GPx-4 is expressed as a mitochondrial, cytosolic, or nuclear isoform. Deletion of the whole GPx-4 gene is lethal: GPx-4 k.o mice die *in utero* at midgestation. Individual deletions of the mitochondrial and nuclear GPx-4 allowed establishing that the nuclear GPx-4 has a marginal role in fertility, contributing to sperm chromatin condensation. The mitochondrial GPx-4 instead is more relevant in this process, the k.o of this form resulting in infertility. By exclusion, therefore, the cytosolic GPx-4 emerges as the essential form for embryonic development and apoptosis regulation.

The role in fertility of the nuclear and mitochondrial GPx-4 is related to its limited specificity for the reducing substrate. During late spermatogenesis, when the GSH levels fall down, mitochondrial GPx-4 uses the thiol groups of SMCP, a Cys-rich protein of the sperm mitochondrial capsule, as alternate reducing substrate. This yields GPx-4 as an enzymatically inactive structural component of the sperm mitochondrial capsule, a process indispensable for appropriate sperm function. Nuclear GPx-4 works similarly on chromatin, but the consequences are less dramatic, nuclear GPx k.o only exhibiting sperm head instability.

On the other hand, lethality due to GPx-4 deletion is apparently related to enzymatic activity on complex lipid substrates. Inducible GPx-4 inactivation reveals 12/15-lipoxygenase-derived lipid peroxidation as the specific downstream event, triggering apoptosis-inducing factor (AIF)-mediated cell death. In agreement with the anti peroxidative functions of GPx-4 first observed *in vitro*, cell death could be prevented by α -tocopherol,

12/15-lipoxygenase inhibitors, or small interfering RNA (siRNA)-mediated AIF silencing. Furthermore, neuron-specific GPx-4 depletion causes neurodegeneration *in vivo* and *ex vivo*, highlighting the primary role of GPx-4 in cell survival.

Conclusions and Future Perspectives

The growing information on the physiological function of GPxs has challenged the concept that proteins of similar sequence and conserved active site are redundant proteins playing similar physiological roles. While the expected antioxidant function of GPx-1 could be validated by k.o animal models, other family members exhibited a series of surprising functions: GPx-4, for instance, resulted to be relevant for fertility by oxidizing specific protein thiols and crucial for survival by inhibiting a lipoxygenase.

Unexpectedly, CysGPxs resulted to be almost as efficient as their Sec-containing homologs in reducing hydroperoxides. The majority of these enzymes, which typically are monomeric and contain a C_R residue within the functional helix, are linked to the thioredoxin and not to the GSH system. The discovery of changes in substrate specificity and mechanism was paralleled by unexpected novel roles of GPxs such as regulation of growth, peroxide sensing, and gene activation. These evidences focus GPxs as crucial players of redox homeostasis and contribute to highlight redox transition as a complementary mechanism to other posttranslational modifications. In the present scenario, understanding the molecular details of these signaling cascades and defining the specific role of the individual GPxs are expected to be extremely rewarding and full of surprises. Further, it appears indeed to be the ground for developing effective strategies to counteract major human pathological processes such as cancer and cerebral degeneration.

Glossary

Advanced glycation end product (AGE) Irreversible end product of nonenzymatic reaction of carbohydrates with protein; it includes fluorescent and nonfluorescent adducts and cross-links in protein.

Advanced lipoxidation end product (ALE) Stable end product of chemical modification of protein by reactive carbonyl intermediates formed during lipid peroxidation reactions.

Amadori adduct or compound First stable product of glycation of protein, a ketoamine.

Glycation Enzymatic or nonenzymatic adduction of a carbohydrate to a biomolecule.

Glycoxidation product AGE formed by a combination of glycation and oxidation chemistry.

RAGE Receptor for advanced glycation end products.

Introduction

Glycation is the most general term describing the adduction of a carbohydrate to another biomolecule, such as a protein, lipid, or DNA. Glycation may occur either enzymatically or nonenzymatically. The common term for enzymatic glycation is glycosylation, for example, formation of a glycosidic bond using a sugar nucleotide donor during synthesis of glycoproteins. The terms nonenzymatic glycation, nonenzymatic glycosylation, or glycation (without a modifier) are commonly used in reference to direct chemical reactions of reducing sugars with proteins, illustrated by the reaction of glucose with lysine residues in protein to form a ketoamine (Amadori) adduct (Figure 1). Glucation, fructation, ribation, etc. are used in reference to glycation by specific sugars.

Although glycation is a reversible reaction, it is considered a first step in the Maillard or browning reaction, which leads to irreversible chemical modification, browning, generation of fluorescence, and cross-linking of proteins during cooking. These same reactions proceed in the body at lower temperature and slower rates during normal aging. The irreversible adducts and cross-links in tissue protein are known as advanced glycation end products (AGEs). Most AGEs are formed by a combination of glycation and oxidation reactions and are termed glycoxidation products. AGEs accumulate gradually with age in long-lived extracellular proteins, such as collagen, and are also formed from glycolytic intermediates on shorter-lived intracellular proteins. Increased rates of formation of AGEs in tissue proteins during hyperglycemia and oxidative stress or inflammation are implicated in the pathophysiology of aging, and diabetes and other chronic diseases.

Glycation of Proteins in Blood

Glycated Hemoglobin

Interest in the Maillard reaction in biochemistry began with the identification of HbA_{1c}, an anodic variant of adult hemoglobin (Hb), discovered during screening of diabetic patients.

HbA_{1c} contains glucose bound to the amino-terminal valine residues of the Hb β -chains. The glucose–valine adduct was characterized as an aminoketose or ketoamine (fructosevaline), formed by nonenzymatic reaction of glucose with protein (Figure 1). The high reactivity of the β -chain valine residues of Hb results from catalysis of the Amadori rearrangement by phosphate or 2,3-bisphosphoglycerate bound near these valine residues in the allosteric site regulating the oxygen affinity of Hb. The α -chain valines, which have similar exposure to solvent and the same low pK_a , but are not in the allosteric site, are only $\sim 10\%$ as glycated as the β -chain valines. Hb has 66 lysine residues, but there are only about twice as many fructoselysine as fructosevaline residues in the protein. The more reactive lysines are adjacent to basic or acidic amino acid in the primary or three-dimensional structure of the protein, which either affect the nucleophilicity of the lysine amino group or catalyze the Amadori rearrangement. The primary sites of glycation of ribonuclease by glucose *in vitro* are at lysine residues in the active site. Glycation of some, but not all, of these residues is catalyzed by phosphate and other anionic buffers that bind in the basic, RNA-binding region of the enzyme. Thus, glycation, although not as specific as enzymatic glycosylation of protein, is not a random modification of protein, but is affected by the pK_a of the amino acid, amino acid sequence, protein conformation, and ligand binding.

Clinical Significance of Glycated Hb

Assays of glycated Hb (GlcHb) are a powerful tool for the clinical management of diabetes. Glycation is a slow reaction. The rate of formation of HbA_{1c} is $\sim 0.1\%$ of HbA molecules per day at normal blood glucose concentration, and is first order in glucose concentration. Since the red cell is long lived (life span ~ 120 days) and freely permeable to glucose, the mean extent of glycation of Hb varies with mean blood glucose concentration. The average percent glycation of Hb ranges from 4% to 6% HbA_{1c} in a control population, to 16% or higher in poorly controlled diabetic patients. Based on clinical studies, assays of percent HbA_{1c} integrate the mean blood

Figure 1 Pathway for glycation of protein. Glucose reacts reversibly with amino groups in protein (e.g., lysine), forming a Schiff base (not shown), which rearranges to the Amadori compound (ketoamine), fructoselysine. Oxidation of the Amadori compound is one route to formation of advanced glycation or glycoxidation end products, such as CML and pentosidine.

glucose concentration during the previous 4–6 weeks. These assays complement acute blood glucose measurements for assessment of long-term glycemic control in diabetes.

Assays for HbA_{1c} use an anion-exchange procedure that depends on the shift in pK_a of the protein, which occurs on glycation of the valine residues. Alternatively, total GlcHb may be measured by an affinity chromatography assay that depends on interaction of Amadori adducts on the surface of the protein with phenylboronate resins; this assay measures glycation of both valine and lysine residues. While assays of HbA_{1c} and GlcHb actually measure different aspects of GlcHb, the two assays yield similar quantitative results and correlate strongly with one another. Both the ion-exchange and affinity chromatography assays are available as mini-column kits. A high-performance liquid chromatography (HPLC) method is commonly used for the measurement of HbA_{1c} in clinical chemistry laboratories, and electrophoretic, nephelometric, and enzyme-linked immunosorbent assay (ELISA) assays are also used.

Glycation of Extracellular and Plasma Proteins

Glucose is ubiquitous in body fluids, and therefore all tissue proteins are subject to glycation. The steady-state extent of glycation of a protein depends on the inherent reactivity of the protein with glucose under physiological conditions, the protein's biological half-life or life span, and the ambient glucose concentration. The fractional glycation of lysine in lens proteins is ~40% that of skin collagen in humans, reflecting the lower glucose concentration in the lens, compared to extracellular fluids. Collagen accounts for about one-third of total body protein mass and is accessible by biopsy. Like glycation of Hb, the extent of glycation of skin collagen may be used as an index of very long term hyperglycemia.

Assays for glycated plasma proteins, which have relatively short half-lives compared to Hb or collagen, provide an index of intermediate-term blood glucose concentration, during the previous 7–10 days. In addition to ELISA and phenylboronate affinity chromatography assays for glycated albumin, total Amadori adducts on plasma proteins can be measured by the fructosamine assay. This assay measures the reduction of a tetrazolium dye by the Amadori compound on plasma proteins. The Amadori adduct has much stronger reducing activity than glucose at pH 10, so that the reducing activity of Amadori adducts on glycated plasma proteins can be measured without significant interference by blood glucose.

Glycation of Other Amino Acids and Biomolecules

Glucose appears to react only with primary amino groups on protein. However, Amadori compounds undergo facile rearrangement and oxidation reactions. They may rearrange nonoxidatively to form deoxyglucosones, regenerating free lysine, or undergo autooxidative decomposition to form glucosone. These dicarbonyl compounds react with the side chains of lysine, arginine, cysteine, and histidine residues, expanding the range of glycative damage to protein. Amadori adducts to phosphatidylethanolamine and phosphatidylserine have also been measured in tissues. The AGE, N²-carboxyethyl-2'-deoxyguanosine, has been detected in DNA of cells grown in high glucose concentration, and was recently reported to be increased in urine of diabetic versus control mice.

Reactivity of Glucose

The rate of reaction of a sugar with protein depends on the fraction of the sugar in the open-chain, aldehyde conformation.

Glucose, among all sugars, exists to the greatest extent in the cyclic, hemiacetal conformation. It is therefore the least reactive in glycation proteins, in comparison to other hexoses, pentoses, ketoses, or phosphorylated metabolic intermediates. Another unique feature of glucose is that it is the least active among all aldoses and ketoses in oxidation or autooxidation (oxidation by molecular oxygen) reactions – again, because it exists largely in a hemiacetal rather than aldehyde conformation. Its low reactivity with protein and its resistance to autooxidation may have been important in the evolutionary selection of glucose as blood sugar in mammals. Despite its chemical inertness, however, glucose does react with proteins at a measurable rate *in vivo* and glycation increases in concert with hyperglycemia in diabetes.

Advanced Glycation and Glycoxidation Reactions

Advanced Glycation

Food scientists learned early in the twenty-first century that glycation was one of the early steps in the Maillard or browning reaction of proteins during cooking, part of the process of caramelization that enhances the color, taste, aroma, and texture of cooked foods. The Maillard reaction also contributes to the loss in nutritional value of cooked foods, because of the chemical modification of essential amino acids, such as lysine and arginine. When biomedical scientists discovered that Hb was glycated *in vivo*, it was reasonable to speculate that advanced stages of the Maillard reaction should also proceed *in vivo* – the human body could be viewed, at one level, as a low-temperature oven (98.6 °F) with a long cooking cycle (~80 years). The Maillard reaction was seen as a possible source of the brown color and fluorescence that develops with age in long-lived proteins, such as lens crystallins and skin collagens, and as a contributing factor in both the normal aging of tissue proteins and the acceleration of age-like pathology by hyperglycemia in diabetes.

More than 20 AGEs have now been detected in tissue proteins (Figure 2), including amines, amides, pyrroles, imidazolones, imidazolium salts, and several bicyclic heteroaromatic compounds. The first two AGEs to be identified *in vivo* were N^ε-(carboxymethyl)lysine (CML) and pentosidine (Figure 1). Because of their stability during acid hydrolysis of proteins, these compounds are still the most frequently measured AGEs. CML is measured by GC/MS (GC, gas chromatography; MS, mass spectrometry) or ELISA, while pentosidine, which is present at much lower concentration, is highly fluorescent and is measured by HPLC. Other AGEs, such as the imidazolones and glucosepane, are present at concentrations comparable to CML, but are measured less frequently because they are labile to acid or base hydrolysis and must be measured following enzymatic digestion of proteins. The known AGEs are only trace components of proteins *in vivo*. Even in skin collagen and lens proteins of elderly diabetic patients, CML and N^ε-(carboxyethyl)lysine (CEL) (Figure 2) typically account for the modification of less than 1% of the lysine residues in the protein. However, these biomarkers are thought to represent only a fraction of the total chemical modification of amino acids and cross-linking of proteins *in vivo*.

Glycoxidation

Although oxygen is not required for glycation, formation of CML and pentosidine from the Amadori compound requires oxidation, for example, oxidative cleavage between C-2 and C-3 of the carbohydrate to form the lysine adduct CML or loss of one carbon from glucose during the formation of pentosidine. These oxidative reactions are catalyzed by trace amounts of free (decompartmentalized) redox-active, metal ions, such as iron and copper. The term glycoxidation was coined in recognition of the importance of both glycation and oxidation in the formation of AGEs. Oxidation reactions often have high-negative free energies, and, especially in oxidative cleavage reactions, oxygen can be viewed as the fixative of irreversible damage to protein during the Maillard reaction. However, some AGEs, such as pyrraline and the crosslines, may be derived from glucose under nonoxidative conditions from deoxyglucosones formed from Amadori compounds under nonoxidative conditions.

Alternative Pathways to AGEs and Glycoxidation Products

In the early 1980s, the Amadori adduct was considered an obligate intermediate in the formation of AGEs (Figure 1). However, it is now clear that there are multiple precursors and pathways to the formation of the same AGE (Figure 3). CML, for example, may be formed from glyoxal or glycolaldehyde which are produced on autooxidation of many carbohydrates, or by autooxidation of Schiff base intermediates and Amadori adducts, or from ascorbate and dehydroascorbate and phosphorylated intermediates in glycolysis. To complicate the issue further, glycolaldehyde formed on oxidation of serine by myeloperoxidase and glyoxal formed during lipid peroxidation reactions may also contribute to the formation of CML. Thus, the measurement of CML provides little information regarding its origin. Lipid-derived adducts to protein, such as malondialdehyde and hydroxynonenal adducts to protein, are known as advanced lipoxidation end products (ALEs), while CML and glyoxal lysine dimer (GOLD), and the homologous compounds, CEL and methylglyoxal lysine dimer (MOLD), are now considered AGEs/ALEs, reflecting the fact that they may be derived from a variety of carbohydrate and noncarbohydrate precursors *in vivo*. Some AGEs, such as pentosidine and the crosslines, which contain five to six carbon rings or side chains (Figure 2), are clearly derived from carbohydrates, but may be formed from a variety of carbohydrate precursors, including reducing sugars, sugar phosphates, and ascorbate. In general, AGEs, ALEs, and other protein oxidation products accumulate together in proteins, for example, in amyloid plaque in neurodegenerative disease.

AGE Receptors, Inhibitors, and Breakers

AGE Receptors

AGEs bind to several proteins, including lactoferrin, macrophage scavenger receptors (MSRs), oligosaccharyl transferase-48 (AGE-R1), 80 K-H phosphoprotein (AGE-R2), galectin-3 (AGE-R3), and the receptor for AGEs (RAGE). Some receptors, such as AGE-R1, AGE-R2, AGE-R3, and MSR, do not transduce

Figure 2 Structure of AGEs that have been detected in tissue proteins by chemical and/or immunological methods: (a) nonfluorescent lysine adducts and cross-links, including amides, amines, and imidazolium salts; (b) fluorescent lysine-lysine cross-links; (c) fluorescent arginine-lysine cross-links; (d) arginine derivatives. CML, N^ε-(carboxymethyl)lysine; CEL, N^ε-(carboxyethyl)lysine; GALA, glycolic acid lysine monoamide; LOMA, lysine oxalic acid monoamide; GOLD and MOLD, GO and MGO lysine dimer (imidazolium salts); and GODIC and MODIC, GO and MGO dihydroimidazolylidene cross-links.

cellular signals after ligation; instead, they cause clearance and detoxification of AGEs. In contrast, binding of AGEs to RAGE initiates proinflammatory signaling cascades. The best-characterized AGE receptor, RAGE, is a member of the immunoglobulin superfamily of cell-surface molecules. It is highly expressed in lung tissue from which it was originally isolated; however, it is also found at lower levels in a wide range of differentiated adult cells. The extracellular domain of RAGE consists of one V-type domain and two C-type domains; the latter form the ligand binding site. The intracellular, cytosolic domain mediates signal transduction. Ligation of RAGE by AGEs results in activation of cell-signaling events, involving mitogen-activated protein kinase (MAPK) and nuclear factor

kappa B (NF-κB). Various members of the MAPK family such as p44/p42 (ERK) MAPK, JNK MAPK, and p38 MAPK induce transcription of proinflammatory target genes. AGE-RAGE interaction also triggers generation of reactive oxygen species, mediated by activation of NF-κB.

RAGE is a cationic, pattern-recognition receptor, probably recognizing both the hydrophobic and anionic character of AGE proteins. Other ligands, such as high-mobility group box-1 protein (HMGB1; known as amphoterin), amyloid-β-protein, and S100/calgranulins also bind to RAGE. Under normal conditions, oxidative stress and protein turnover induced by ligation of RAGE may have a role in the remodeling and rejuvenation of tissues; however, this process may become

Figure 3 Alternative sources of the AGEs/ALEs. CML may be formed from reducing sugars, either directly by oxidative cleavage of Schiff base or Amadori adducts on protein, or indirectly through glyoxal or glycolaldehyde formed on oxidation of glucose or glucose adducts to protein. CML may also be formed from ascorbate, through glyoxal, glycolaldehyde, or tetroses formed on oxidative degradation of dehydroascorbate. Glyoxal or glycolaldehyde are also formed during peroxidation of polyunsaturated fatty acids, or during myeloperoxidase-mediated degradation of amino acids.

pathogenic in chronic disease. RAGE is upregulated when its ligands accumulate in tissue and its expression is increased in pathological conditions, such as diabetes, vascular and neurodegenerative disease, consistent with a role for overstimulation of RAGE in the pathogenesis of chronic inflammatory diseases.

Both protein and small molecule RAGE antagonists are being evaluated as therapeutic agents for limiting inflammatory damage in chronic disease. Small molecule inhibitors include compounds that block AGE–RAGE interaction, down-regulate RAGE expression, or block RAGE-mediated signal transduction in model systems. Binding of AGEs to RAGE, both *in vivo* and *in vitro*, can also be inhibited by an excess of soluble RAGE (sRAGE), the extracellular domain of RAGE. Because it lacks the cytosolic and transmembrane domains of RAGE, sRAGE traps ligands in the intracellular space, inhibiting cell binding and signal transduction. None of these agents has completed evaluation in clinical trials.

AGE Inhibitors and Breakers

AGE inhibitors do not affect glycation of proteins, but inhibit formation of AGEs. These compounds, such as aminoguanidine and pyridoxamine, generally have a reactive amino or thiol group that traps reactive carbonyl intermediates in AGE formation. AGE breakers are more complex nucleophilic compounds that are designed to cleave pre-existing AGEs in proteins. There is some controversy about their mechanism of action since AGE breakers also have AGE inhibitor and chelating (antioxidant) activity. However, the beneficial effects of AGE inhibitors and breakers are perhaps the most convincing evidence for the role of AGEs in disease – these compounds protect against the full range of renal, retinal, neural, and

vascular complications in animal models of diabetes. AGE breakers also reverse vascular stiffness in elderly persons with cardiovascular disease, independent of diabetes. Other activities of AGE breakers and inhibitors may contribute to their efficacy *in vivo*, since some of them inhibit amine oxidases, including some isoforms of nitric oxide synthase, have chelating activity, and also have antihypertensive and hypolipidemic effects *in vivo*. Some AGE inhibitors do not have reactive functional groups that would trap carbonyl intermediates, suggesting that chelation may be their primary mechanism of action. Indeed, the chelators trientine (triethylenetetramine) and citrate have been shown to protect against diabetic complications in animal models.

The Maillard Reaction in Aging and Disease

Aging

The age-dependent browning of tissue proteins is most apparent in the lens, which becomes visibly yellow with age. This change in color is accompanied by insolubilization, aggregation, and precipitation of lens crystallins, which may proceed to the formation of cataracts. Collagens and other long-lived proteins in the body undergo similar changes with age. The increased cross-linking of collagen contributes to the decrease in elasticity and resiliency of the extracellular matrix with age. By interfering with turnover of matrix components by metalloproteinases, browning reactions may also contribute to the age-dependent thickening of microvascular basement membranes, for example, in the retina and kidney, affecting the permeability and transport properties of the extracellular matrix. The accumulation of AGEs in long-lived proteins (Figure 4) is accompanied by an age-dependent increase in protein fluorescence and by a parallel increase in other chemical modifications of proteins, including products of both nonoxidative (e.g., aspartate racemization and spontaneous deamidation) and oxidative damage (*o*-tyrosine, nitrotyrosine, dityrosine, and methionine sulfoxide). Research on the Maillard hypothesis today is focused on increasing evidence that AGEs have effector functions, that is, they activate or participate in physiological responses to stress, including inflammation, hyperglycemia, hyperlipidemia, and oxidative stress. Although proteins serve as the register or accumulator of Maillard reaction damage *in vivo*, glycoxidative and oxidative modifications of DNA may have significant effects on the integrity of the genome during aging.

Diabetes

The glycation, AGE, or Maillard hypothesis identifies glucose as the culprit in diabetes, and proposes that diabetic complications result from accelerated Maillard reaction damage to tissue protein. Consistent with the hypothesis, both the extent of glycation of protein and the rate of accumulation of AGEs are accelerated by hyperglycemia in diabetes (Figure 4). The damage, such as hyperglycemia, is systemic, and age-adjusted levels of AGEs in skin collagen are correlated with the severity of renal, retinal, and vascular complications of diabetes. The Maillard hypothesis is a chemical rather than metabolic theory on the origin of diabetic complications; it explains the development

Figure 4 Influence of age and diabetes on glycation and glycoxidation of skin collagen: (a) glycation of protein is reversible and relatively constant with age. Glycation of collagen increases with mean blood glucose concentration and correlates with GlcHb in diabetic patients; (b) and (c) the concentrations of the AGE/ALE, CML, and of the AGE, pentosidine, increase with age in the nondiabetic population and at an increased rate in diabetic patients; (d) despite differences in origin and mechanism of formation and significant differences in their concentrations, the levels of CML and pentosidine in skin collagen correlate more closely with one another than with age in either control or diabetic populations. Reproduced from Dyer DG, Dunn JA, Thorpe SR, et al. (1993) Accumulation of Maillard reaction products in skin collagen in diabetes and aging. *Journal of Clinical Investigation* 91: 2463–2469, with permission.

of similar complications in both type 1 (juvenile-onset, insulin-dependent) and type 2 (adult-onset, noninsulin-dependent) diabetes, despite the differences in etiology of these diseases (insulin deficiency vs. insulin resistance). It also explains the development of complications in the kidney, nerve, retina, and vasculature, since intracellular glucose concentration in the endothelial and parenchymal cells in these tissues tracks extracellular glucose concentration. These tissues are also rich in long-lived extracellular proteins, such as collagens, elastin, and myelin. In addition to the gradual accumulation of AGEs on extracellular proteins, AGEs are also formed on intracellular proteins in these tissues, probably from glycolytic intermediates, such as the triose phosphates. Research on intracellular glycation and AGE formation is still at an early stage, but is essential for a comprehensive understanding of the role of the Maillard reaction in the pathogenesis of diabetic complications.

Other Diseases

AGEs and ALEs are increased in tissues in a wide range of age-related, chronic diseases, including diabetes, atherosclerosis, dialysis-related amyloidosis, arthritis, and neurodegenerative diseases. The increase in glycoxidative and lipid-derived (lipoxidative) modifications reflects, in part, uncontrolled chemistry occurring, either locally or systemically, in biological systems as a result of increased substrate (carbohydrate or lipid),

decreased antioxidant defenses, and/or increased decompartmentalization of metal ions. Although the AGEs/ALEs are not the primary source of pathology in these diseases, they are macrophage chemoattractants and proinflammatory molecules, acting as both intermediaries in pathogenic processes and biomarkers of resultant tissue damage. AGE/ALE inhibitors may eventually prove useful for limiting damage or complications from a wide range of chronic, age-related diseases. Their effects on health and longevity are being explored in studies in animal models.

Glossary

Acyltransferases Enzymes that transfer fatty acids from thioester linkage in acyl-coenzyme A to O-ester linkage in molecules such as glycerol phosphate.

Anionic lipids Lipid molecules with a net negative charge.

Ether lipids Lipid molecules characterized by ether rather than ester linkages between glycerol and hydrophobic substituents.

Glycerolipids Lipid molecules consisting of a glycerol backbone structure to which are coupled in ester, or ether, or glycosidic linkages, fatty acids, fatty alcohols, saccharides, and phosphate esters.

Neutral uncharged lipids Lipids without substituents having a formal charge.

Zwitterionic lipids Lipid molecules with multiple functional groups having both negative and positive charges.

Introduction

Lipids, along with proteins, carbohydrates, and nucleic acids, constitute one of the major groups of biochemicals found in all eukaryotic cells. Among the lipids, glycerolipids are the most abundant family and these molecules have numerous functions within cells that range from energy storage, to structural compartmentation of cells and organelles, to key signaling activities that are essential for regulating cell growth and development. This article focuses upon the structure, functions, and biosynthesis of the glycerolipids, and identifies the interfaces of this information with other articles in the encyclopedia.

Glycerolipid Structure

The structures of all eukaryotic glycerolipids are fundamentally based upon the structure of *sn*-glycerol-3-phosphate, which is shown in [Figure 1](#) and illustrates the stereospecific numbering (*sn*) of each carbon. The *sn*-glycerol-3-phosphate molecule is asymmetric and optically active; when drawn in a Fisher projection, the chiral *sn*-2 position has the OH group on the left side of the molecule. The absolute stereoconfiguration assigned using the Cahn, Ingold, and Prelog method is 2-*R*-glycerol-3-phosphate. With few exceptions, in animal eukaryotic cells that are not specialized in fat storage, or predisposed to fat storage due to developmental programming, or pathological abnormalities, the major glycerolipids are phosphate containing and typically referred to as 'glycerophospholipids', or more simply as 'phospholipids'. In cells specialized in fat storage, such as mammalian adipocytes, the major glycerolipids are triacylglycerols (TAGs).

The general structural features of glycerophospholipids are outlined in [Figures 1](#) and [2](#). Esterification of fatty acids to the *sn*-1 and *sn*-2 carbons of *sn*-glycerol-3-phosphate produces the lipid phosphatidic acid (PtdOH). Phosphatidic acid is a minor phospholipid constituent of many eukaryotic cells and is used as a metabolic intermediate in the synthesis of additional glycerolipids. Phosphatidic acid is a phosphomonoester that can condense with a variety of alcohols to produce a phosphodiester linkage commonly found in the more complex phospholipids

(see [Figure 2](#)). The main alcohols that give rise to these structures are choline, ethanolamine, serine, inositol, and glycerol. The mature phospholipids that arise from these condensations are phosphatidylcholine (PtdCho), phosphatidylethanolamine (PtdEtn), phosphatidylserine (PtdSer), phosphatidylinositol (PtdIns), and phosphatidylglycerol (PtdGro). The terminal hydroxyl group of PtdGro can also form a phosphodiester with another molecule of PtdOH to produce a Ptd₂Gro, a lipid with the common name of cardiolipin. Cardiolipin is also referred to as diphosphatidylglycerol; however, a more accurate name is *bis*-phosphatidyl-glycerol, although it is not commonly used.

Additional forms of glycerolipids, which lack phosphate, are also found throughout eukaryotic organisms. In TAG, the phosphate substituent of PtdOH is replaced by a fatty acid esterified to the *sn*-3 position of glycerol (see [Figure 3](#)). Variations upon this latter structural theme also occur in which a glycerol contains only two fatty acids (diacylglycerols (DAGs)) or one fatty acid (monoacylglycerol). One major grouping of glycerolipids (glycosyl-glycerolipids) is highly abundant in eukaryotic plants and consists of a DAG moiety conjugated to a galactose monomer, a galactose dimer, or a sulfo-galactose monomer.

The structures of glycerolipids confer important physical properties upon the molecules. The fatty acid substituents contain relatively long hydrocarbon chains (typically 16–22 carbons, with 0–6 double bonds), which are hydrophobic and sequestered away from aqueous environments. The phosphate and polar alcohol, or sugar constituents are hydrophilic and readily interact with aqueous solvents. This dual or amphipathic property of glycerolipids causes them to form large, non-covalent complexes, such as micelles and bilayer sheets, when the lipids are introduced into aqueous environments. Molecules such as TAG have no hydrophilic domains and these lipids efficiently form phases that completely segregate away from aqueous environments, with minimal interaction. The fatty acids esterified to the glycerol backbone of phospholipids can dramatically affect the physical properties of these molecules in membranes. Membranes harboring lipids containing fatty acids with few double bonds tend to be more rigid, whereas those with fatty acids containing large numbers of double bonds tend to be more fluid. These bulk properties can significantly alter

the interactions of membrane proteins with each other, and with substrates or ligands the proteins recognize.

A number of variations occur to the basic structures of the common phospholipids described above and are important elements in the biology and function of the molecules. One unusual structural variant contains long-chain fatty alcohols in place of the long-chain fatty acids that occur in the hydrophobic portions of lipid molecules (see Figure 4). In these molecules, the ester linkage that usually couples fatty acids to the glycerol is replaced by an ether linkage. From a simple chemical perspective, this ether linkage imparts much greater chemical stability to the chemical bond. Within the class of ether lipids, a subset of the molecules contains a double bond adjacent to the ether linkage, and lipids with this characteristic are generally named 'plasmalogens', for historical reasons. In another type of structural variation, hydroxyl groups present in PtdIns are available for further modification. One of the most important modifications to PtdIns is the attachment of phosphate groups to the 3, 4, and 5 positions of the inositol ring. Although these phosphorylated forms of PtdIns are present at very low levels within cells, they play crucial roles in

regulating membrane recognition events and controlling a variety of physiological processes within cells. The hydroxyl groups of PtdIns can also be modified by the attachment of fatty acids, and these modifications also play an important role in regulating the behavior of specific membrane proteins.

Another structural variant of the phospholipids shown in Figure 2 is built upon the same *sn*-glycerol-3-phosphate backbone, but contains only one fatty acid esterified to either the *sn*-1 or *sn*-2 hydroxyl group. This modification occurs in conjunction with any of the aforementioned polar alcohols or saccharides described earlier. Broadly, these lipids are referred to as lyso-phospholipids. As an example, a glycerolipid with a fatty acid esterified to the *sn*-1 position, an unesterified hydroxyl at the *sn*-2 position, and a choline moiety esterified to the *sn*-3 phosphate is named 'lyso-phosphatidylcholine' (see Figure 5). The lyso moniker historically derives from fractions of phosphatidylcholine that were isolated by column chromatography and shown to be capable of lysing red blood cells. Many lyso-phospholipids have significant detergent activity that renders them lytic to cell membranes when the lipids are present in sufficiently high concentrations. The generic term 'lyso-phospholipid' does not specify which hydroxyl on the glycerol phosphate backbone is esterified, and forms with acyl groups esterified to either the *sn*-1 or *sn*-2 hydroxyls are commonplace. Lyso-PtdOH, lyso-PtdCho, lyso-PtdEtn, lyso-PtdSer, lyso-PtdIns, and lyso-PtdGro and lyso-Ptd₂Gro are all present in biological systems, usually at low levels. Lyso-Ptd₂Gro can occur as a variety of structural forms, with either one (monolyso-) or two (dilyso-) unesterified hydroxyls. Another variation upon the lyso-phospholipid structures occurs in which two monoacylglycerols are coupled in a single phosphodiester linkage. The resultant molecule is a *bis*-monoacylglycerol-phosphate. Many lyso-phospholipids are generated by the actions of phospholipase A enzymes, which hydrolyze the ester bonds of fatty acids esterified to the *sn*-1 or *sn*-2 positions of glycerol phosphate backbones of

Figure 1 Structures of *sn*-glycerol-3-phosphate and phosphatidic acid. *sn*-glycerol-3-phosphate forms the structural scaffold for the glycerolipids and phosphatidic acid is the major root structure for all of the glycerolipids. The *sn*-1, *sn*-2, and *sn*-3 positions are designated within the circles.

Figure 2 Glycerophospholipids share common structural features in their phosphatidic acid moiety. The coupling of the phosphatidic acid structure with the alcohols, choline, ethanolamine, serine, inositol, and glycerol defines the majority of glycerophospholipids in eukaryotic cells.

phospholipids. Lysophospholipids can occur either as biosynthetic intermediates or as degradation products in biochemical pathways.

Glycerolipid Functions

A complete list of specific functions of glycerolipids would greatly exceed the space available for this article. A few examples will be provided for each of the major and minor glycerolipids. One of the most far-reaching aspects of phospholipid function is their intrinsic ability to form membrane bilayer structures in aqueous environments. This membrane-forming action is essential for cells to define the boundaries that separate them from their environment and demarcate intracellular compartments (organelles) for specialized intracellular function.

PtdOH is a minor anionic phospholipid present in cell membranes that plays crucial roles in regulating the activity of enzymes involved in controlling cell growth. Many of these proteins play crucial roles in promoting the growth of cancer cells. PtdOH has also been identified as a lipid that sequesters regulatory proteins necessary for turning specific genes on and off. Increases or decreases of the PtdOH levels within the cell can have profound effects upon the activation of specific genes.

PtdCho is the most abundant phospholipid in cell membranes of many eukaryotes ranging from yeast to mammals. PtdCho is zwitterionic and typically functions as the major structural lipid of most membranes. A specialized molecular species of PtdCho containing palmitic acid esterified to both the *sn*-1 and *sn*-2 positions of the molecule (dipalmitoyl-PtdCho) is present in pulmonary surfactant, and forms a film at the air tissue interface of the lung, in the alveolar region where oxygen absorption occurs, and greatly reduces the work

of breathing. The lack of dipalmitoyl-PtdCho can cause respiratory failure in premature newborns.

PtdEtn typically constitutes the second most abundant phospholipid in eukaryotic cell membranes. This zwitterionic lipid plays an important role in cell division and is associated with the process whereby the membrane of a parent cell pinches off to form two daughter cells. In the mammalian eye, PtdEtn becomes modified during the visual cycle, and abnormal processing of this modified lipid can lead to macular degeneration.

PtdSer is a minor cellular lipid with anionic character. Although its total cellular concentration is not high, specific membrane compartments, such as the inside surface of the plasma membrane, are highly enriched in this lipid. PtdSer plays an important role in the early steps of blood clotting. Platelets within the blood expose PtdSer on the outside of their surface membrane to initiate the blood clotting process. In addition, the appearance of elevated levels of PtdSer on the outside of the surface membrane of numerous types of cells functions as a biochemical signal that attracts immune cells to the site for the purpose of engulfing and destroying these cells.

PtdIns is also a minor cellular lipid, which is anionic. This lipid can bind several regulatory proteins and influence the synthesis of PtdCho. PtdIns serves as an important precursor for the formation of phosphorylated derivatives known as 'polyphosphoinositides', especially PtdIns-3-P, PtdIns-4-P, PtdIns-4,5-P₂, and PtdIns-3,4,5-P₃. The different polyphosphoinositides play important roles in regulating intracellular membrane traffic, by binding specific proteins that regulate dynamic aspects of membrane structure, function, and interaction.

PtdGro is also a minor anionic, cellular lipid, which, in most cells, functions primarily as a precursor for the synthesis of cardiolipin. In the lung, PtdGro is an important component of pulmonary surfactant, where it functions as an inhibitor of inflammatory processes elicited by a variety of pathogens.

Ptd₂Gro is a lipid that is restricted to mitochondria where it functions as a cofactor in the association of proteins in the respiratory chain to form large macromolecular complexes. A specific molecular species of cardiolipin containing four linoleic acids esterified to the backbone *sn*-glycerolphosphates is markedly reduced in patients with the X-linked disease known as Barth syndrome. The mitochondria from individuals afflicted with this disorder exhibit abnormal structure and function.

TAG is the major storage form of fat. Within adipocytes, TAGs essentially phase-separate from the cytosol and form oil droplets. The limiting membrane of lipid droplets plays a crucial role in orchestrating the formation of the droplet and regulating the metabolism of the stored TAGs.

Figure 3 Glycerolipids without phosphate are of major importance. Two examples of glycerolipids without phosphate are shown. Triacylglycerol is the major storage form of fat and diacylglycerol is a crucial intermediate in glycerolipid synthesis and cell signaling pathways.

Figure 4 Structural features of ether linked glycerolipids. Two examples of ether-linked variants of phosphatidic acid are shown. The alkyl lipids have an ether bond with the *sn*-1 carbon of the *sn*-glycerol-3-phosphate scaffold. The alk-1'-enyl lipids have an ether bond with the *sn*-1 carbon of the scaffold and also contain a double bond adjacent to the ether linkage.

Figure 5 Structural features of lyso-phospholipids. Lyso-phospholipids lack one of the two acyl chains typical of glycerophospholipids, and lyso-PtdOH and lyso-PtdCho are shown for structural comparison.

DAGs are usually present in only trace quantities within cells. Much of the DAG pool within cells serves as a precursor for the synthesis of lipids such as PtdCho, PtdEtn, and TAG in mammalian cells. However, there is also a highly dynamic and rapidly metabolized pool of DAG associated with signaling events at the plasma membrane that occur in conjunction with hormone or growth-factor activation of cell surface receptors. This localized DAG pool plays an important role in activating protein kinases that regulate cell growth.

Bismonoacylglycerolphosphate (BMP) is an unusual lipid that is highly enriched in endosomes, multivesicular bodies, and lysosomes. The biophysical properties of this lipid indicate that it plays an important role in membrane fusion events within the endosomal system.

Glycerolipid Synthesis

Bioenergetic Considerations

The stepwise assembly of glycerolipids from precursor molecules, like all biosynthetic reactions, requires chemical energy. Ultimately, this energy source can be traced back to adenosine triphosphate (ATP), but this article focuses upon the energetics of the reactions proximal to the formation of end products. The formation of esters between fatty acids and the hydroxyl groups of glycerol utilizes the chemical potential energy stored in the thioester bond of acyl-coenzyme A (CoA) derivatives. The free energy of hydrolysis of the thioester bond between fatty acids and CoA is nearly equivalent to that of ATP.

The formation of phosphoester linkages at the *sn*-3 position of glycerol comes from ATP for the formation of PtdOH. The formation of PtdCho and PtdEtn utilizes the energy of pyrophosphate cleavage of the cytidine 5'-diphosphate (CDP) conjugated alcohols CDP-choline and CDP-ethanolamine to form the *sn*-3 phosphodiester linkages. The synthesis of anionic lipids, PtdSer, PtdIns, PtdGro, and Ptd₂Gro, utilizes the energy of pyrophosphate cleavage of CDP-diacylglycerol to form the *sn*-3 phosphodiester linkages. Some eukaryotes execute hydrophilic head group exchanges for the synthesis of PtdSer, PtdEtn, and PtdCho. The polyphosphoinositides use ATP for the direct formation of phosphomonoesters at positions 3, 4, and 5 of PtdIns.

Phosphatidic Acid Synthesis

The initiation of glycerolipid synthesis begins at a branch-point from glycolysis and utilizes the common intermediate, dihydroxyacetone phosphate (DHAP), which is derived from the aldolase cleavage of fructose-1,6-bis-phosphate. The

major synthetic reactions for the glycerolipids are summarized in Figure 6. DHAP is reduced to *sn*-glycerol-3-phosphate by glycerol-3-phosphate dehydrogenase. The first fatty acid is attached to the glycerol backbone by *sn*-glycerol-3-phosphate acyltransferase (GPAT), using an acyl-CoA substrate and yielding the product lyso-PtdOH. Some forms of this enzyme in mammalian systems show a preference for saturated fatty acids and they are located in different organelles including endoplasmic reticulum, mitochondria, and peroxisomes.

An alternative route to the formation of lyso-PtdOH commences with acylation of the available hydroxyl of DHAP, also using an acyltransferase enzyme and an acyl-CoA substrate, yielding the product acyl-DHAP. This acyl-DHAP can next be reduced by nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxidoreductase to produce lyso-PtdOH. The acylation of DHAP and its subsequent reduction occur in the peroxisome. A second fatty acid is esterified to lyso-PtdOH by the action of another family of acyltransferases, using an acyl-CoA substrate. PtdOH is a biosynthetic intermediate at a crucial juncture of glycerolipid metabolism. One branch of the pathway gives rise to PtdCho, PtdEtn (together comprising the neutral zwitterionic glycerolipids), TAG, and glycosyl-DAG (together comprising the neutral uncharged glycerolipids) and the other branch gives rise to the anionic phospholipids, PtdSer, PtdIns (and its phosphorylated derivatives), PtdGro, and Ptd₂Gro. There are important differences between lower eukaryotes (e.g., *Saccharomyces cerevisiae*) and mammals in the synthetic pathways for the anionic glycerophospholipids.

Anionic Glycerophospholipid Synthesis

The committed step for diverting PtdOH to the anionic glycerophospholipid biosynthetic pathway is the synthesis of cytidine 5'-diphosphate-diacylglycerol (CDP-DAG) (see Figure 6). Pyrophosphate cleavage of cytidine 5'-triphosphate (CTP) provides the chemical energy to couple the cytidine 5'-monophosphate (CMP) nucleotide to PtdOH, and the reaction is catalyzed by CDP-DAG synthase. The enzyme shows dual localization to both the endoplasmic reticulum and the mitochondria. In the endoplasmic reticulum, the CDP-DAG is a substrate for the synthesis of PtdIns catalyzed by PtdIns synthase. Upon cleavage of the pyrophosphate bond, the PtdOH moiety forms a phosphate ester linkage with the C1-position hydroxyl of inositol. The resultant PtdIns accounts for approximately 90% of the inositol lipids in mammalian cells. Further metabolism of PtdIns can proceed via the ATP-dependent enzymes, PtdIns-3kinase, PtdIns-4kinase, and PtdIns-5kinase reactions, yielding at least five different types of polyphosphoinositides. These reactions are highly regulated and additional biochemical details are given elsewhere in this encyclopedia.

The mitochondrial pool of CDP-DAG is used for the synthesis of PtdGro and Ptd₂Gro. The synthesis of PtdGro occurs in a two-step reaction at the inner mitochondrial membrane. In the first step, the PtdGro synthase enzyme utilizes CDP-DAG and *sn*-glycerol-3-phosphate as substrates for the synthesis of PtdGroP. In this reaction, the PtdOH moiety is esterified to the *sn*-1 position of *sn*-glycerol-3-phosphate. In the second step, the terminal phosphate of the PtdGroP is hydrolyzed to yield PtdGro. The steady-state level of PtdGro in mitochondria

Figure 6 Major synthetic pathways for the synthesis of glycerophospholipids. DHAP derived from glycolysis generates the scaffold for both diacyl and ether lipid synthesis. PtdOH resides at a crucial branchpoint in lipid synthesis segregating anionic glycerolipids from neutral zwitterionic and uncharged lipid synthesis. CDP-DAG functions as the central precursor for anionic glycerophospholipids and DAG functions as the central precursor for zwitterionic glycerophospholipids and glycerolipids without charged groups. This schematic is a composite of the important reactions occurring in lower and higher eukaryotes and plants.

is low because most of this lipid is used for the synthesis of Ptd₂Gro via a reaction catalyzed by cardiolipin synthase, which utilizes PtdGro and CDP-DAG as substrates. In this latter reaction, the cleavage of the pyrophosphate of CDP-DAG is coupled to the esterification of the PtdOH group to the free sn -3 hydroxyl group present in PtdGro.

In many eukaryotes, but not mammalian systems, CDP-DAG is also used as a precursor for PtdSer. As in the other CDP-DAG reactions, the cleavage of the pyrophosphate linkage is accompanied by transfer of the PtdOH moiety to the alcohol acceptor, which is the primary hydroxyl group of serine. The reaction catalyzed by PtdSer synthase occurs in the endoplasmic reticulum. This reaction has been most completely studied in yeast. Mammalian cells use a different strategy for the synthesis of PtdSer in which the alcohol head groups of PtdCho and PtdEtn are exchanged for serine. The regulation of the mammalian pathways is not well understood, but may be coupled to localized calcium flux. Two enzymes have been identified, one of which uses both PtdCho and PtdEtn as sources of the PtdOH moiety and the second which preferentially uses PtdEtn.

The anionic glycerophospholipid family of eukaryotes contains 13 prominent members as shown in Figure 6. CDP-DAG serves as the essential biosynthetic precursor for the production of 10 different classes of anionic glycerophospholipids.

Despite this large number of different types of anionic glycerophospholipids, the entire family constitutes a relative minority of lipids within cells usually comprising less than 25% of total cellular glycerophospholipids. The physical characteristics of these lipids, their documented specific interactions with a variety of regulatory proteins, and their specialized localization within specific organelles all contribute to the biological importance of these lipids.

Neutral Zwitterionic and Uncharged Glycerolipid Synthesis

The second arm of the branchpoint occurring from the central PtdOH intermediate in animal eukaryotes gives rise to the neutral zwitterionic glycerolipids, PtdEtn and PtdCho, as well as the uncharged glycerolipid, TAG (see Figure 6). In plants, the dominant glycerolipids are monogalactosyl- and digalactosyl-DAG. This latter point merits particular emphasis, since digalactosyl-DAG is estimated to be the single most abundant lipid class present on the Earth. The committed metabolic step that shunts the PtdOH intermediate away from anionic glycerolipid synthesis is catalyzed by PtdOH phosphatase. The PtdOH phosphatase is a highly regulated enzyme because it not only directs biosynthesis in the direction of the major structural lipids of all eukaryotic cell membranes (PtdEtn and PtdCho) but also provides the necessary precursor for TAGs,

Figure 7 Remodeling reactions adjust the fatty acids attached to phospholipids. The fatty acid content of phospholipids is not static. A combination of phospholipase removal of a fatty acid (R_2 in this example) and lysophospholipid acyltransferase-catalyzed replacement with a different fatty acid (R_3 in this example) functions to adjust phospholipid structure to meet specific needs of different organelles, and the changing environmental and developmental demands.

which are the major and most efficient storage form of calories in nearly all eukaryotes. The product of the PtdOH phosphatase reaction is DAG. Similar to the role of CDP-DAG as a central precursor of anionic glycerolipid synthesis, DAG functions as a central intermediate supplying multiple crucial pathways for the nonanionic glycerolipids.

In the biosynthetic reactions utilizing DAG, the chemical energy driving the reactions is derived from a variety of substrates that participate in the transfer of groups to the primary alcohol of this lipid. For PtdEtn synthesis, the substrate is CDP-Etn. The enzyme ethanolamine phosphotransferase catalyzes the cleavage of the pyrophosphate bond in CDP-Etn and transfers the P-Etn moiety to the *sn*-3 hydroxyl position of DAG. This reaction occurs principally in the endoplasmic reticulum. An alternative route for the synthesis of PtdEtn utilizes the anionic phospholipid, PtdSer, as a substrate for the enzyme PtdSer decarboxylase. Both pathways for the synthesis of PtdEtn are active across the phylogenetic spectrum of eukaryotes. For many organisms, the PtdSer decarboxylase enzyme is localized to the mitochondria and plays a major role in providing PtdEtn for this organelle.

The synthesis of PtdCho from DAG is analogous to that for PtdEtn and utilizes the substrate CDP-Cho. The choline phosphotransferase also uses pyrophosphate cleavage to transfer the P-Cho from the water-soluble substrate, to the *sn*-3 hydroxyl of the DAG lipid. In general, this reaction is limited by the availability of CDP-Cho. The choline phosphotransferase is principally localized to the endoplasmic reticulum. Many eukaryotes are also capable of synthesizing PtdCho by methylating the primary amine of PtdEtn catalyzed by PtdEtn methyltransferases. In yeast, these methyltransferase reactions are highly active and can produce all of the PtdCho required for cell growth. The methyl donor in these reactions is S-adenosyl-methionine (SAdoMet). In mammalian systems, the PtdEtn methyltransferase is most active in liver tissue, and either marginally active or undetectable in other tissues.

TAG is also derived from DAG and this constitutes the major pathway for storing calories in the form of fat. The enzyme DAG acyltransferase utilizes an acyl-CoA substrate, and cleavage of the thioester bond of the substrate is coupled to esterification of the fatty acid to the *sn*-3 hydroxyl of the glycerolipid. Two DAG acyltransferases are the major contributors to TAG synthesis in mammalian systems in most tissues. One of these enzymes, DGAT1, is more promiscuous in its use of acceptors and can utilize monoacylglycerols and retinols in addition to DAG as substrates for transfer of acyl groups. The DAG acyltransferases localize principally to the endoplasmic reticulum, but may also be found in regions of the organelle that give rise to lipid droplets. DAG acyltransferase in

plants also gives rise to TAG, which is of significant economic importance in the generation of seed oils that have major importance in nutritional, industrial, and biofuel applications.

The DAG intermediate in plants also functions as the major metabolic precursor of the glycosyl-DAGs. The conversion of DAG to galactosyl-DAG is catalyzed by the corresponding galactosyl transferase. This reaction uses uridine 5'-diphosphate (UDP)-galactose as the water-soluble substrate, and the cleavage of the UDP moiety is coupled to the transfer of the galactose to the *sn*-3 hydroxyl of the DAG. Typically, the one carbon of galactose is coupled in β linkage to *sn*-3 hydroxyl of the glycerol backbone. Synthesis of higher-order galactolipids, such as digalactosyl-DAG, occurs through a similar mechanism of transfer of galactose from the nucleotide sugar to the galactosyl-DAG, with the terminal galactose in α -1,6 linkage to the first galactose. Although plants also synthesize the major phospholipids found in eukaryotes, the bulk of their membrane lipids consists of the galactolipids, a situation which probably evolved as a mechanism for plants to survive in phosphate-limited environments.

Ether Lipid Synthesis

As described earlier in this article, the lipid repertoire of some organisms, including mammals, contains ether-linked glycerolipids. These lipids are synthesized in a manner similar to that of the more abundant ester-linked glycerolipids, but with several unique steps. The early steps in ether lipid synthesis are confined to the DHAP backbone rather than the *sn*-glycerol-3-phosphate backbone. Acyl-DHAP is the required substrate for the synthesis of ether lipids, and the enzyme alkyl-DHAP synthase catalyzes an exchange of a long-chain fatty alcohol for the fatty acid esterified at the *sn*-1 position (see Figure 6). The resultant alkyl-DHAP product is reduced by an oxidoreductase that uses NADPH as a coenzyme. The next step in the pathway introduces a fatty acid into the *sn*-2 position by the action of an acyl transferase. The final product from the above steps is an analog of PtdOH that differs from the di-ester form, by the presence of an ether linkage connecting the hydrophobic aliphatic chain at the *sn*-1 position of the molecule (see Figure 4). This ether version of PtdOH is further processed for the synthesis of major phospholipids by many of the same pathways used for the di-ester version of the molecule. One additional reaction unique to ether lipid synthesis is the introduction of a double bond in the hydrocarbon chain adjacent to the ether linkage at the *sn*-1 position. The substrate for this reaction is 1-alkyl-2-acyl-*sn*-glycerol-3-phosphoethanolamine, and a desaturase enzyme introduces a double bond between the first and second carbons of

the alkyl chain using electrons derived from NADPH. The product is 1-alk-1'-enyl-2-acyl-*sn*-glycerol-3-phosphoethanolamine, and this molecule is often referred to as an ethanolamine plasmalogen for historical reasons. Further metabolism of this unsaturated ether lipid can give rise to the PtdCho version of the molecule, which is also generically referred to as a choline plasmalogen. Choline plasmalogens constitute a significant portion of the total phospholipids present in heart tissue.

Phospholipid Remodeling

The lipid synthetic reactions outlined in [Figure 6](#) are largely focused upon the pathways that alter the substituents attached to the *sn*-3 position of the glycerol backbone, and give rise to the major classes of the glycerolipids. From the scheme, it might appear that the acyl groups found esterified to the *sn*-1 and *sn*-2 positions at the level PtdOH might be the same found for all of the other lipid classes. However, this is not the case, since the fatty acids found in the *sn*-1 and *sn*-2 positions of PtdOH are not identical to those found in PtdCho, PtdEtn, PtdSer, PtdIns, and the polyphosphoinositides, PtdGro, Ptd₂Gro, TAG, and MGDAG. A similar situation applies to the *sn*-2 fatty acids in ether lipids. One major contributor to these differences is the process of lipid remodeling (see [Figure 7](#)). In its simplest form, remodeling is a process in which a molecule such as PtdCho undergoes a cycle of removal of one type of acyl group (perhaps a mono-unsaturated fatty acid) from the *sn*-2 position by a phospholipase A₂ to form a lyso-PtdCho, followed by attachment of a different acyl group (perhaps a polyunsaturated fatty acid) at the *sn*-2 position catalyzed by a lyso-PtdCho acyltransferase. Remodeling of phospholipids is one mechanism of ensuring that specific organelles contain the precise types (molecular species) of phospholipids to execute unique functions. The remodeling process is not restricted to the *sn*-2 position of phospholipids, but can also occur at the *sn*-1 position. Furthermore, the remodeling activities occurring in one cellular membrane (e.g., mitochondria) are not the same as remodeling reactions occurring at different membranes (e.g., Golgi). Current information suggests that remodeling occurs for all different types of phospholipids and that specific classes of phospholipids, such as PtdCho, can be remodeled by multiple acyltransferases with different selectivity for specific fatty acids.

Glossary

Gephyrin This is derived from the Greek word for bridge and alludes to the fact that the protein anchors the glycine receptor (GlyR) to the subsynaptic cytoskeleton.

Ligand-gated ion channels (LGICs) Family of receptor proteins composed of homologous subunits, whose intrinsic ion channel opens after binding of neurotransmitter.

Startle disease Human hereditary disorder characterized by an exaggerated startle reaction in response to unexpected stimuli.

Strychnine A plant alkaloid derived from the Indian tree *Strychnos nux vomica*. Potent convulsant antagonizing glycinergic inhibition.

Glycinergic inhibition of neuronal excitability in spinal cord and brain stem is mediated via inhibitory glycine receptors (GlyRs). These receptors are composed of two types of homologous membrane-spanning subunits (α and β) and belong to the pentameric nicotinic acetylcholine receptor superfamily of ligand-gated ion channels. Binding of presynaptically released glycine to postsynaptically enriched GlyRs prevents membrane depolarization of nerve cells by opening receptor-intrinsic chloride channels and is specifically antagonized by the convulsant alkaloid strychnine. Mutations in GlyR genes give rise to neuromotor and startle disorders in humans and animals and underline the important roles of GlyRs in motor coordination and sensory processing.

Glycine, the simplest of all amino acids, has diverse functions within the mammalian central nervous system (CNS). It inhibits postsynaptic neurons via strychnine-sensitive glycine receptors and, together with glutamate, enhances neuronal excitation by the activation of excitatory *N*-methyl-D-aspartate receptors (NMDARs). Currents of both receptors are potently modulated by the divalent cation Zn^{2+} , an endogenous modulator of inhibitory glycinergic neurotransmission. Recent studies indicate that a distinct combination of NMDAR subunits is activated by glycine alone, and thus functions as an excitatory glycine receptor. Our results establish complex roles of glycine and Zn^{2+} at this unconventional NMDAR family member. In summary, glycine regulates neuronal excitability via different receptors located at inhibitory and excitatory synaptic connections.

Distribution of Glycine in the Brain

Although glycine is the simplest of all amino acids, it has diverse functions within the CNS. It serves as an inhibitory neurotransmitter at the GlyR and as a co-agonist essential for the activation of excitatory NMDARs, in addition to being involved in the metabolism of proteins and nucleotides in all cells. The regional levels of glycine in the CNS mainly reflect its role in inhibitory neurotransmission, being highest in the medulla oblongata, pons, and spinal cord, and lowest in the cerebral hemispheres and the cerebellum.

Physiological Role and Functional Properties of Glycine Neurotransmission

Principal Properties of Glycinergic Inhibition

Excitation of glycinergic neurons in the CNS causes Ca^{2+} triggered release of presynaptic glycine into the synaptic cleft and results in the activation of postsynaptic GlyRs, which mediate an increase in the chloride conductance of the postsynaptic plasma membrane (Figure 1). These glycinergic synaptic currents have a complex time course with a fast rising phase and an exponential deactivation, which reflect the synchronous activation of GlyR channels by glycine released during exocytosis and the subsequent closure of individual channels, respectively. After receptor unbinding, glycine is removed from the synaptic cleft by rapid reuptake into presynaptic nerve terminals or surrounding glial processes to allow termination of the transmission process (Figure 1).

Roles in Spinal Control of Motor Activity and Sensory Processing

Inhibition at central synapses is mediated by both glycine and γ -aminobutyric acid (GABA). Whereas GABA is primarily used in higher brain regions, glycinergic synapses are particularly abundant in spinal cord and brain stem, that is, structures involved in the control of motor rhythm generation, the coordination of spinal reflex responses, and the processing of sensory signals. Ia glycinergic interneurons in spinal cord mediate reciprocal inhibition in stretch reflex circuits, allowing relaxation of the antagonist muscle, and thus contribute to the coordination of opposing muscles. Renshaw interneurons regulate motoneuron excitability by producing a recurrent inhibition via a negative feedback system. In sensory processing, glycine modulates neuronal circuits in the auditory system and in the retina and suppresses nociceptive signals in the spinal cord.

Synaptic versus Extrasynaptic Inhibition and the GlyR in Higher Brain Regions

Although neurotransmission between nerve cells is mainly mediated by synaptic contacts, GlyRs are also found

using adsorption of the detergent-solubilized receptor on aminostrychnine-agarose followed by elution with the agonist glycine. The resulting preparation contained the pentameric GlyR composed of α and β -subunits and the associated anchoring protein gephyrin.

Glycine Receptor Isoforms

Cloning of GlyR subunit complementary DNAs (cDNAs) revealed that the GlyR belongs to the same superfamily of group I ligand-gated ion channels as the nicotinic acetylcholine receptor (nAChR), the GABA type A (GABA_AR), the serotonin type 3 receptor (5-HT₃R), and the glutamate-gated-chloride channel receptor (GluClR). The GlyR α - and β -subunits share significant sequence homology with each other (>40%) and, to a lesser extent, with other proteins of the nAChR family. Homology is particularly high within the four transmembrane domains and a cysteine-rich loop located within the N-terminal extracellular region. Four different genes encoding GlyR α -subunits (α 1–4) have been identified in vertebrates with an overall sequence identity of >80%. Alternative splicing in the extracellular N-terminal region and in the intracellular loop between transmembrane domains 3 and 4 generates further diversity. So far, only a single GlyR β -subunit gene has been found.

Spatial and Developmental Expression of GlyR Subunits in the Brain

In situ hybridization studies revealed that α 1 GlyR subunit mRNA is mainly found in spinal cord, brain stem, and the colliculi, whereas GlyR α 2-transcripts are found in the hippocampus, cerebral cortex, and thalamus (see also Figure 2). Low levels of α 3-mRNA are detected in spinal cord, cerebellum, olfactory bulb, and hippocampus. The β -subunit gene is expressed throughout the entire CNS. Expression of α -subunits is subject to developmental regulation; α 1-transcripts increase, and α 2-mRNA decreases, after birth. This change in mRNA expression is reflected in an altered GlyR subunit composition and a faster decay time of inhibitory glycinergic postsynaptic currents. The neonatal form primarily composed of α 2-homooligomers exhibits long channel open times, while the adult isoform is a α 1 β -heterooligomer characterized by fast channel kinetics.

Heterologous Expression of the GlyR

After heterologous expression, all GlyR α -subunits form functional homooligomeric channels with properties resembling those of native GlyRs. Single expression of the β -subunit does not result in either glycine-activated currents or [³H]strychnine binding. Coexpression of α - and β -subunits generates heterooligomeric GlyRs that differ from homooligomeric α GlyRs by their insensitivity to the channel blocker picrotoxinin and a reduced main state conductance.

Structural Features of the GlyR

Cross-linking of native receptors, biochemical results, and pharmacological responses of heterologously expressed receptors

have shown that GlyR pentamers are composed of two α 1 and three β -subunits, which have molecular masses of 48 kDa and 58 kDa, respectively. All subunits share a large and highly conserved N-terminal extracellular domain, four putative transmembrane domains (M1–M4), and a short extracellular C-terminus (Figure 2). All four transmembrane segments are α -helices. Structural models of the GlyR have been aided by crystal structures of pentameric ligand-gated ion channels ELIC (RCSB Protein Database entry 2VL0) and GLIC (PDB 3EAM) from bacteria and of the GluClR from *Caenorhabditis elegans* (PDB 3RHW).

Molecular Model of the Ligand-Binding Region

Sequence homology within the group I ligand-gated ion channel superfamily and the crystal structure of the homologous soluble acetylcholine binding protein from the snail *Lymnaea stagnalis* (PDB 1I9B) allows for experimentally validated models of conserved ligand-binding sites. These are located at the extracellular interface between subunits and involve amino acid residues that belong to distinct loops of two adjacent subunits. This site in the GlyR has been described in reasonable detail.

Ion Channel Function

The second transmembrane domain M2 forms the ion channel of the GlyR. It is highly anion-selective, with a halide selectivity sequence of $I^- > Br^- > Cl^-$, and is significantly permeable to bicarbonate. A characteristic of GlyRs is that they do not exhibit a single conductance state but instead display a range of conductance states, with residue Gly 254 within the second transmembrane domain constituting a major determinant of ion flux (Figure 2). Heterooligomeric α 1/ β GlyRs show lower subconductance state levels than α 1 homomeric receptors, and in this respect resemble the adult native receptors.

The Cytoplasmic Loop of the β -Subunit Is Crucial for Postsynaptic Receptor Clustering

A protein of 93 kDa, named gephyrin, copurifies with the GlyR and is enriched on the cytoplasmic face of the postsynaptic membrane. A short amino acid motif within the cytoplasmic loop linking the third and fourth transmembrane domains of the GlyR β -subunit forms the binding site for gephyrin. Thus, synaptically localized GlyR is bound via its β -subunit to the submembraneous scaffold protein gephyrin, which interacts with cytoskeletal and other synaptic proteins, and thereby targets and anchors the GlyR to postsynaptic membrane specializations (Figure 1).

Pharmacological Properties of the GlyR

The Classical Antagonist Strychnine

The alkaloid strychnine constitutes a unique tool in the investigation of the GlyR. In electrophysiological studies, it is the most reliable antagonist to distinguish glycinergic from GABAergic inhibition. Biochemists use glycine-displaceable [³H]strychnine binding to quantify the GlyR in

Figure 2 Phylogenetic relationships between and transmembrane topology of vertebrate GlyR subunits. (a) Evolutionary relationships between GlyR subunits. In addition to individual subunits, the chromosomal localizations of the human genes and their major sites of expression are indicated. (b) Transmembrane topology of the human GlyR α 1 subunit, with amino acid residues mutated in human hyperekplexia (gray residues) being indicated. Conserved cysteine residues forming disulfide bridges are shown in black. Residue N38 constitutes the sole N-glycosylation site. Mutation A52S is found in the *spasmodic* mouse. G254 in M2 of the α 1-subunit determines the main conductance and sensitivity to the channel blockers CTP, ginkgolides, dihydropyridines, and chlorinated insecticides. Residue D80 is an important determinant of Zn^{2+} potentiation, whereas residues H107, H109, and T112 are essential for Zn^{2+} inhibition. Secondary structure predictions for the extracellular and transmembrane domains are indicated by amino acid residues arranged in β -sheet (β 1– β 10), or α -helical (M1–M4), structures, respectively.

radioligand-binding assays. The physiological symptoms of strychnine poisoning emphasize the importance of glycinergic inhibition in the control of both motor behavior and sensory processing. Due to its high toxicity, which causes convulsions and, at higher doses, death, strychnine is of low therapeutical value but serves as a rat poison.

Agonistic Amino Acids

In addition to glycine, the endogenous amino-acids β -alanine and taurine display inhibitory activity when applied to neurons. Taurine released nonsynaptically from immature cortical neurons has been found to influence cortical development by activating extrasynaptic GlyRs. Antagonism of taurine reuptake increases GlyR currents, whereas antagonism of β -alanine reuptake has little effect, and thus the role of β -alanine is unclear. Both β -alanine and taurine are partial agonists, which can elicit only submaximal currents.

Antagonism by Channel Block

The alkaloid picrotoxinin acts as a use-dependent but voltage-independent open-channel blocker of the GlyR and can be used to discriminate homo- from heterooligomeric receptors. Hetero-oligomeric GlyRs composed of α and β -subunits are relatively resistant to block by picrotoxinin, whereas homo-oligomeric GlyRs containing only α -subunits are sensitive to low micromolar alkaloid concentrations. Several compounds block the GlyR channel apparently by binding deep within the pore. These include the bulky organic anion cyanotriphenylborate (CTB), plant-derived ginkgolides, dihydropyridines (typically used as calcium channel blockers), and chlorinated compounds used as insecticides (that target insect GABA receptors).

Allosteric Modulation of the GlyR

The number of agents known to potentiate GlyR function is increasing. Therapeutically, potentiation of glycinergic inhibition in the mammalian CNS has substantial promise for both normalizing pathological states and for lowering sensory and motor activity under different conditions including narcosis. The selectivity of allosteric modulators is as yet insufficient to target specific GlyR subtypes.

Anesthetics and alcohol

Since decades, anesthetics and alcohols are known to potentiate GlyR responses. Anesthetic concentrations of propofol and volatile halogenated hydrocarbons such as halothane, enflurane, isoflurane, methoxyflurane, and sevoflurane enhance the effects of low concentrations of glycine at the GlyR. The potencies of n-alkohols increase with chain length of their alkyl groups, up to a cutoff value of twelve carbon atoms. Using site-directed mutagenesis, residues within the transmembrane domains have been shown to be important for the potentiating effect of anesthetics and alcohol.

Glutamate

Paradoxically, the classic excitatory neurotransmitter glutamate has been shown to enhance the response of GlyR to glycine.

This is perhaps of particular significance in the brain, where high levels of glutamate might increase the effect of otherwise insignificant concentrations of glycine. Together with the agonist activity of glycine at certain NMDARs, this complicates the simple idea of excitatory receptors for glutamate and inhibitory receptors for glycine and GABA.

Zinc

The divalent cation Zn^{2+} exhibits biphasic effects on both native and recombinantly expressed GlyRs. Low concentrations of Zn^{2+} (0.1–10 μ M) potentiate submaximal glycine-induced currents about threefold, while higher concentrations cause inhibition. Since Zn^{2+} is present within presynaptic secretory vesicles and is coreleased with the neurotransmitter upon stimulation, this modulation might be of considerable physiological significance. Mutational studies indicate that the Zn^{2+} binding sites for potentiation and inhibition are located at subunit interfaces, as are the agonist binding sites (see also Figure 2).

Neurosteroids, anesthetics, and cannabinoids

Steroids markedly affect glycinergic transmission; however, their actions are variable and show a strong dependence on subunit composition. This does, however, provide an interesting therapeutic lead. *In vivo*, steroid effects on GlyR activity may be particularly important around birth and during adolescence. Anesthetics depress the nervous system partly by enhancing inhibitory neurotransmission. For example, certain effects of propofol require GlyRs, and this correlates with the enhancement of recombinant GlyRs by low concentrations of propofol. Similarly, analgesic effects of endogenous and exogenous cannabinoids (including Δ^9 -tetrahydrocannabinol from cannabis) are due to their enhancement of GlyR function. All three of these classes seem to interact with the GlyR membrane-bound helices.

Ivermectin

The large macrocyclic lactone ivermectin is an anthelmintic that activates invertebrate GluClRs and to a lesser extent mammalian GlyRs. The effects of ivermectin are interesting, because it seems to activate the chloride channel by binding in the transmembrane domain, thus forgoing the canonical extracellular ligand-binding domain. This may help describe what conformational changes are required in channel opening, and the structure–activity relationships of ivermectin at different Cys-loop receptors provides potential leads for subunit-selective macrocyclic lactones.

Posttranslational modifications

GlyR subunits contain consensus sequences for glycosylation (see Figure 2), phosphorylation (protein kinases A and C, Ca^{2+} -dependent kinases), and ubiquitination. Although a regulation of GlyR channel activity by phosphorylation was observed in different preparations, consistent with a potential role of protein kinases in the modulation of synaptic efficacy, the functional significance of GlyR phosphorylation is far from being clear. Also, ubiquitin-mediated internalization and degradation of the GlyR have been suggested to constitute important mechanisms for regulating receptor numbers in the neuronal plasma membrane. Editing of $\alpha 3$ GlyRs in the

hippocampus results in highly sensitive glycine receptors that alter neuronal excitability and may contribute to diseases such as temporal lobe epilepsy.

Disorders of Glycinergic Neurotransmission

Mutations in GlyR subunits causing an impairment of glycinergic transmission result in neurological malfunction and hereditary neuromotor disease.

Human Disorders

The first disorder associated with a mutation in a neurotransmitter receptor was found by positional cloning. Hyperekplexia (startle disease, Kok disease) is characterized by muscle rigidity of nervous system origin, particularly in neonates, and by an exaggerated startle response to unexpected auditory or tactile stimuli. The underlying genetic defect was mapped to chromosome 5q by genetic linkage using DNA markers defining the glycine receptor $\alpha 1$ gene GLRA1 as the prime candidate. Substitutions of the charged residue Arg 271 by uncharged amino acids (Leu or Gln) were identified in four families with autosomal dominant hyperekplexia. These substitutions result in a reduction of agonist sensitivity and glycine-activated current. Recombinant expression of the mutant GlyRs revealed that the reduced glycine current is due to a decrease in single-channel conductance levels. Recessive forms of hyperekplexia have subsequently been identified in other families, which carry other missense or null mutations in the GLRA1 locus (see [Figure 2](#)). However, in only 40–50% of the human patients displaying hyperekplexia-like symptoms GLRA1 mutations have been found, suggesting that genes other than GLRA1 could be involved in hyperekplexia.

Animal Mutants

The syntenies between human chromosome 5q and mouse chromosome 11 led to the discovery that recessive mutations in mouse GLRA1 underlie two mouse neurological mutants, *spasmodic* and *oscillator*. *Spasmodic* displays a phenotype similar to human hyperekplexia and is caused by missense mutation of Ala 52 to Ser (see [Figure 2](#)). *Oscillator* has a more severe phenotype, including progressive tremor and muscle spasms, leading to death by 3 weeks of age. Lethality is caused by a

frameshift-producing deletion predicted to eliminate the large cytoplasmic loop and the fourth transmembrane domain. Homozygous *spastic* mice develop at about 2 weeks postnatally a hyperekplexic phenotype that is associated with a marked reduction in the density of GlyRs in brain stem and spinal cord. The disorder results from the insertion of a LINE-1 element into an intronic region of the gene encoding the β -subunit of the GlyR (GLRB), thereby causing delayed and aberrant splicing of the β -subunit mRNA. A disease resembling the human and murine startle diseases is found in Poll-Hereford cattle and Peruvian Paso horses. These animals display strong myoclonus resulting from reduced or absent glycine receptor expression in the spinal cord. In the Poll-Hereford cattle, a missense mutation at Thr24 of the GlyR $\alpha 1$ gene has been shown to cause translational stop, and thus a complete $\alpha 1$ subunit deficiency in homozygous animals.

Glycogen Metabolism

P J Roach, Indiana University School of Medicine, Indianapolis, IN, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Enzyme A protein that catalyzes or accelerates chemical reactions, such as those involved in metabolism, to interconvert compounds in cells.

Hormone A compound in the blood released from specialized organs, called endocrine glands, which acts as a messenger within the body to regulate the function of individual target tissues.

Metabolism The process by which molecules are interconverted within cells among different related chemical forms, called metabolites.

Pancreas An organ with multiple functions related to the utilization of foods. The endocrine pancreas responds to the nutrient levels in the blood to release the hormones insulin and glucagon.

Glycogen Structure

Many nutrients contain either glucose or compounds that are easily converted to glucose, so that it is an important nutritional currency for many organisms. Glycogen is a glucose polymer, meaning that individual glucose units are joined together by repeated chemical linkages to form large molecules containing thousands of glucose residues (Figure 1). Two types of linkages are present in glycogen causing a branched polymeric structure. These same two linkages are present in plant starches which serve a similar function as glycogen. When needed, the glucose units can be recovered by breaking down the glycogen. A possible explanation for the storage of glucose as glycogen rather than glucose monomers is due to the lower osmotic activity of the polymer. Some minor constituents of glycogen, such as covalently attached phosphate, have also been noted.

Glycogen Metabolism

Glycogen exists as a particle in which the carbohydrate core is associated with several of the proteins needed to make it and degrade it. The glycogen molecule expands or contracts due to growth or breakdown of the outer branches of the molecule (Figure 1).

Synthesis

Glycogen in cells is synthesized either directly from glucose transported into the cells by transporter proteins or from other cellular metabolites that are converted to the activated sugar precursor, uridine diphosphate (UDP)-glucose in animals and adenosine diphosphate (ADP)-glucose in bacteria (or for starch biosynthesis in plants). Three enzymes are needed to synthesize glycogen: an initiator protein called glycogenin that attaches glycogen residues to itself, the enzyme glycogen synthase responsible for incorporating most of the glucose moieties of glycogen from UDP-glucose, and a special enzyme, branching enzyme, to introduce the branch points (Figure 2).

Degradation

Controlled degradation of glycogen requires two enzymes (Figure 2). Glycogen phosphorylase releases a glucose unit from the polymer as a metabolite, called glucose-1-phosphate, that can be used by the cell. Since phosphorylase stalls at the branch points, a second specialized enzyme, the debranching enzyme, is needed to degrade past them. In muscle, the process stops at another metabolite of glucose, called glucose-6-phosphate, which is used in the muscle cell to provide energy or building blocks. In liver, the glucose-6-phosphate can be converted, by an enzyme called glucose-6-phosphatase, to free glucose that is exported to the bloodstream. There is a second pathway to degrade glycogen. In most cell types, there is a house-cleaning process whereby a portion of the cellular content is continuously being delivered to an organelle, called lysosome or vacuole, to recycle the building blocks of the macromolecules, for example, amino acids from proteins and glucose from glycogen. A specialized enzyme, called an α -glucosidase, is present in the lysosome to break glycogen down to glucose.

Glycogen Function and Control

Metabolic Role

Whether in bacteria or mammals, glycogen serves as a reservoir of energy and/or building blocks that can be called upon in times of need. In microorganisms, glycogen is generally made in response to impending nutritional deprivation, as judged by sensing the composition of the environment, and stored for use late in starvation. In mammals, the nutritional cues that govern glycogen metabolism in tissues are indirect and are borne by the blood levels of glucose itself and several important regulatory molecules called hormones. After a meal, nutrients enter the gut and lead to increased blood glucose, which triggers the pancreas to release the hormone insulin, a signal of the fed condition. Insulin-sensitive tissues – liver, fat, and especially skeletal muscle – respond by increasing transport of glucose into the cells (Figure 3(a)). Insulin also causes activation of the enzyme glycogen synthase, enhancing the conversion of glucose to glycogen. This is part of the process

of blood glucose homeostasis whereby the body seeks to maintain the blood glucose level within safe limits. As the time after the last meal increases, the blood glucose level normalizes; the pancreas delivers less insulin and begins to secrete the hormone glucagon, which signals the unfed state (**Figure 3(b)**). The primary target is the liver which responds by breaking down glycogen to produce glucose that can be delivered to the bloodstream, another contribution to blood glucose homeostasis.

Role in Muscle or Exercise

Unlike the liver, muscle cannot break down glycogen all the way to free glucose for export to the bloodstream. Muscle glycogen is instead broken down to metabolites that can be converted to energy to fuel muscular contraction. The stimulus for the breakdown of muscle glycogen is the same as for contraction, and nerve signals instructing the muscle to contract concurrently activate glycogen phosphorylase, which

breaks down glycogen. Most muscles do not rely entirely on glycogen and other fuels, such as fat, can also be utilized. Increased muscular activity is often associated with increased levels of the stress hormone, epinephrine (also called adrenaline). In response to anxiety, which in evolution might have involved fleeing an aggressor, the adrenal gland produces epinephrine which activates phosphorylase in muscle and liver, providing, respectively, enhanced muscle performance and increased fuel to the bloodstream. Muscular activity also sensitizes the tissue to insulin and activates glycogen synthase, so that it is ready to reform glycogen once contraction ceases.

Glycogen and Disease

Glycogen Storage Diseases

A number of genetic diseases are known in which genes encoding various enzymes involved in glycogen metabolism are mutated (**Table 1; Figure 2**). These diseases range in severity from relatively mild to early death. Their frequency is for the most part relatively low. Most of these diseases are associated with overaccumulation of glycogen or the formation of abnormally branched glycogen. One disease, glycogen storage disease 0, is associated with mutations that impair liver glycogen synthesis and patients are prone to low blood glucose (hypoglycemia). Lafora disease, a progressive myoclonus epilepsy, is characterized by the formation of Lafora bodies in neurons and other tissues. Lafora bodies contain large amounts of poorly branched glycogen and may be caused by impaired metabolism of the small amount of phosphate found in glycogen.

Diabetes Mellitus

Diabetes occurs when blood glucose homeostasis fails and blood glucose levels are elevated. High blood glucose (hyperglycemia) leads to many complications including heart,

Table 1 Selected glycogen storage diseases (GSD)

GSD type	Name	Enzyme affected	Affected organ(s)	Glycogen	Description
0					
Ia	Von Gierke disease	Glycogen synthase Glucose-6-phosphatase	Liver Liver	Reduced amount Normal structure, increased amount	Hypoglycemia Massive liver enlargement, multiple metabolic problems, treatment improving
II	Pompe disease	Lysosomal α -glucosidase	All	Increased glycogen in lysosomes	Usually death before age of 2
III	Cori disease	Debranching enzyme	Muscle, liver	Short outer branches, increased amount	Similar to type I, but less severe
IV	Andersen disease	Branching enzyme	Liver	Long outer branches, normal amount	Usually death from liver failure before age of 2
V	McArdle disease	Muscle glycogen phosphorylase	Muscle	Normal structure, moderate increase in amount	Impaired exercise capability
VI	Hers disease	Liver glycogen phosphorylase	Liver	Increased amount	Similar to type I but less severe
	Lafora disease	Laforin, malin	Brain, many others	Reduced branching	Epilepsy, fatal

kidney, nerve, and eye disease. This disease is both extremely common and growing in epidemic fashion as enrichments in diets around the world are coupled with diminished physical activity and obesity. The more prevalent form, type 2 diabetes, has a genetic component, likely linked to multiple genes, and an environmental component, lack of exercise and unhealthy diet. Type 2 diabetes is associated with an impaired ability to store glucose as glycogen, but whether there is a causal relationship with defective glycogen metabolism is still not certain.

Glossary

Glycogen A complex, branched polymer of glucose that serves as a site of short-term glucose storage as well as a source of blood glucose during fasting.

Hypoglycemia The clinical condition of low blood glucose levels with physiologic consequences including seizures caused by brain dysfunction.

Myopathy Disease of the muscle, in this context reflecting inadequate glucose (and, hence, energy) supply or mobilization from glycogen stores.

Phosphorolysis The use of phosphate to remove successive glucose residues from the reducing end of the glycogen polymer.

Glycogen Structure

As shown in **Figure 1**, glycogen is composed of a large number of glucose polymers with ($\alpha 1 \rightarrow 4$) linkages that are branched with ($\alpha 1 \rightarrow 6$) linkages every 4–10 units. The resulting particles, called β -particles, can become large and contain 6×10^5 individual glucose monomers; these can be grouped into even larger particles called α -particles. The β -particles are organized around a central protein called glycogenin, upon which the initial glucose polymerization is based and thus glycogen is technically a large glycoprotein in which the carbohydrate predominates. There is also a thin bounding membrane that appears to contain most of the enzymes of glycogen metabolism. These particles often can be seen in electron micrographs. Glycogen is found mainly in liver and muscle.

Glycogen Function

Glycogen is a source of glucose for both muscle and liver. As such, it serves as a short-term buffer for glucose homeostasis (liver) and as a source of immediate glucose for energy (muscle). The synthesis and degradation of glycogen are closely regulated. Consistent with glycogen's central role in homeostasis, these processes are controlled by different enzyme systems and hormones. Synthesis is not the reverse of degradation and most of the enzymes catalyze reactions strongly in favor of their products (i.e., they are not at equilibrium). Several of the enzymes are regulated by covalent modification.

Glycogen Metabolism

Figure 2 presents a summary of the pathways involved in glycogen metabolism. Note that several are unique to either liver or muscle. Considerable metabolic control is also exerted on these enzymes as shown.

Glycogen Synthesis

The first committed step in glycogen synthesis is the formation of uridine diphosphate (UDP) glucose by UDP glucose pyrophosphorylase. The glycogen polymer begins with the attachment of glucose to the protein glycogenin. UDP glucose is the substrate for polymerization via ($\alpha 1 \rightarrow 4$) linkages catalyzed by glycogen synthase. The branching enzyme is bifunctional, cleaving the linear chain and creating a branch via an ($\alpha 1 \rightarrow 6$) linkage. This leads to a reduced length of the final polymer and the production of more termini – leading to a more compact particle and providing a substrate suitable for very rapid degradation.

Glycogen Degradation

Most individual glucose residues are removed from the glycogen polymer by phosphorolysis. Different phosphorylase enzymes catalyze this reaction in muscle and liver. These proteins are genetically unique – synthesized from different loci. Muscle phosphorylase has been studied in particularly great detail. It functions as a dimer and contains sites for both covalent and allosteric modifications. Phosphorylase must itself be phosphorylated to be active, a reaction catalyzed by phosphorylase kinase (which is dependent on modification by a cyclic adenosine monophosphate (cAMP)-dependent kinase and calcium).

Due to the branched nature of mature glycogen, either muscle or liver phosphorylase by itself can only partially degrade the polymer. Phosphorylase cannot cleave beyond four glucose residues from the branch point. Glycogen subjected to treatment with phosphorylase alone is converted into limit dextran – which is a still very large molecule. The action of the debranching enzyme eliminates the barrier to phosphorolysis by transferring the three distal glucose residues from the side chain to the nonreducing terminus of the parent chain. This leaves a single glucose remaining from the side chain attached by an $\alpha 1 \rightarrow 6$ linkage. The debranching enzyme also hydrolyzes this remaining side chain residue freeing a single glucose molecule and leaving a continuous

Figure 1 (a) Details of glycogen polymer showing linear ($\alpha(1\rightarrow4)$) and branch ($\alpha(1\rightarrow6)$) linkages. (b) Example of glycogen at lower resolution showing branches and reducing and nonreducing ends.

chain connected by $\alpha(1\rightarrow4)$ linkages, a substrate suitable for phosphorylase.

The products of glycogen degradation are thus predominantly glucose-1-phosphate and a small amount of free glucose from hydrolysis of the single remnant glucose of the side chain. The reversible phosphoglucomutase converts glucose-1-phosphate to glucose-6-phosphate. Because glucokinase is irreversible, the glucose-6-phosphate enters the endoplasmic reticulum (ER) by its own transporter. Within the liver ER, the glucose-6-phosphate is hydrolyzed and the free glucose is then transported out of the cell. Glucose-6-phosphatase is largely confined to the liver and thus the degradation of glycogen in muscle is not a source of blood glucose.

Control of Glycogen Metabolism

Because of the irreversibility of many of the enzymes involved and consideration of the details of **Figure 2**, the synthesis and degradation of glycogen do not use the same pathways. Furthermore, the enzymes mediating both sets of reactions are under tight control. This control is often mediated by adding or removing phosphate to and from the proteins as shown. Several critical control points are

1. The phosphorylated form of glycogen synthase (noted as "b" in the figure) is activated by removing the phosphate to give the "a" form by the active form of phosphoprotein phosphatase. The latter is produced by phosphorylation using adenosine triphosphate (ATP), stimulated by insulin.
2. Phosphorylase is active in its phosphorylated form, produced by the active form of phosphorylase kinase and ATP.

3. Phosphorylase kinase itself is activated by phosphorylation by cAMP-dependent protein kinase A.
4. The active, phosphorylated forms of both phosphorylase kinase and phosphorylase are inactivated through removal of the activating phosphate by the active form of phosphoprotein phosphatase as shown.

Thus, modification of existing enzymes regulates glycogen metabolism. This exquisitely sensitive system is subject to hormonal control. For example, a rise in insulin (the "fed" state with high blood glucose levels) activates phosphoprotein phosphatase (by phosphorylation). This enzyme then activates glycogen synthase and inactivates both phosphorylase and phosphorylase kinase, resulting in the synthesis and accumulation of glycogen.

By contrast, in the "fasting" state (low blood glucose levels) insulin levels are low, inactivating phosphoprotein phosphatase. Other hormones – glucagon and epinephrine – activate cAMP-dependent protein kinase A which phosphorylates (thereby activating) phosphorylase kinase. The latter, in turn, activates phosphorylase itself by phosphorylation leading to glycogen degradation.

This complex but sensitive system provides a critical buffer for blood glucose under common, relatively short-term conditions.

Defects in Glycogen Metabolism and Their Consequences

The remarkably sensitive metabolic system based on glycogen is central to normal physiology and is an essential defense

Figure 2 Metabolic pathways directly involved in the synthesis and degradation of glycogen. Note that blood glucose (top) is both the source of substrates for glycogen synthesis as well as the product of glycogen degradation. Compounds in ovals are biochemical intermediates. The rectangle represents the endoplasmic reticulum (ER) and the hexagonal structure represents a lysosome. Small closed circles show three sites for participation by the phosphorylated form of phosphoprotein phosphatase, formed by insulin stimulation. The small, closed square shows the site of stimulation by glycogen and epinephrine through cAMP-dependent protein kinase A. The sites of enzyme defects in GSDs are indicated by the bold roman numerals. ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; P_i, inorganic phosphate; PP_i, inorganic pyrophosphate; UDP, uridine diphosphate; UTP, uridine triphosphate.

against wide fluctuations in blood glucose levels. Therefore, defects in the pathway are often manifested by failure of glucose homeostasis with the frequent development of symptomatically low blood glucose levels (hypoglycemia). Furthermore, the sheer mass of glycogen polymers that develop when its degradation is inadequate can lead to organ enlargement and, ultimately, dysfunction. Inadequate mobilization of glucose from glycogen can also limit muscle contractility, especially in acute events.

The central position of blood-borne glucose in the energy metabolism of many organs (especially the brain) has meant that careful management of glucose levels is often a prime consideration in the care for affected individuals. We will

consider this group of disorders through reference to [Figure 2](#) and [Table 1](#). It is of historic interest that the definition and biochemical characterization of many of the enzymes in this system were based on detailed study of affected individuals. Although general features of individual types are presented, it is important to remember that the genetic changes underlying the disorders both within and among clinical categories are not uniform. Much clinical heterogeneity likely reflects the fact that different mutations are often responsible for the failure or dysfunction of a given enzyme in different kindreds. This latter fact also complicates diagnostic studies that rely on mutation analysis alone. Several of the categories are often recognized by eponyms as shown.

Table 1 The glycogen storage diseases

<i>Designation</i>	<i>Enzyme</i>	<i>Eponym</i>	<i>OMIM#</i>	<i>Map location</i>
Ia	Glucose-6 phosphatase	von Gierke	232200	17q21

Data from Mendelian Inheritance in Man catalog (OMIM).

Type I (von Gierke)

Originally described in 1929, individuals with this group of disorders have early difficulties with low blood glucose levels (hypoglycemia). In the neonatal period, this can lead to seizures. Slightly later, liver enlargement is detected. Early biochemical study of the liver of affected individuals showed defective activity of glucose-6-phosphatase. Subsequent study of more individuals with similar manifestations revealed more details of the pathway.

Type Ia

This, the largest fraction of affected individuals, is notable for defects in the gene and protein for glucose-6-phosphatase, which have been confirmed by molecular study. Subsequently, however, it was determined that the active site of glucose-6-phosphatase lies within the ER and that hepatic microsomes from some affected individuals could degrade glucose-6-phosphate after detergent treatment. Thus, a transport process was implicated.

Type Ib

These individuals not only have aberrant glucose homeostasis but also have susceptibility to certain infections due to neutrophil and macrophage dysfunction. Cloning and characterizing mutations in the glucose-6-phosphate translocase identified the problem in this group. Although it had been proposed that a third group had defective phosphate transport (and had been given the designation Ic), recent analysis has shown that most of these individuals have mutations already identified in the same translocase as in Ib. The translocase itself is now recognized to have a dual role as an antiporter – mediating both heterologous (glucose-6-phosphate: inorganic phosphate (P_i)) and homologous (P_i:P_i) exchanges. This is consistent with the fact that hydrolysis of glucose-6-phosphate within the ER leads to a local increase in P_i as a product which can then be exchanged for more glucose-6-phosphate substrate to continue the process.

Although the possible existence of another, independent phosphate transporter has been proposed to account for another way of achieving the same clinical picture, there is yet no convincing evidence for this. Thus, a putative type Id has not been conclusively identified.

The care of individuals affected with glycogen storage disease (GSD) Ia/b is similar and is initially based on prevention of hypoglycemia by frequent feedings, often with the use of a slowly hydrolyzable glucose polymer (e.g., cornstarch). Liver transplantation has also been used. The long-term complications of this group of disorders are still being determined, but the prognosis has been considerably improved with adequate control of blood glucose levels.

Type II (Pompe)

This type of GSD is unique because it involves dysfunction of an intralysosomal enzyme – α -1,4-glucosidase (also called acid maltase). The characteristic feature of this group of individuals is accumulation of glycogen within lysosomes. Historically, type II GSD was the first of the so-called “lysosomal storage diseases” to be defined. It is important to recall that glycogen storage and the enzymes for its synthesis and degradation (except for glucose-6-phosphatase) are found in the cytoplasm. It has been proposed that lysosomes take up cytoplasmic glycogen and hydrolyze it within their unique low pH environment.

Intralysosomal accumulation of glycogen in GSD II individuals is more notable in muscle than in liver and, thus, many of the manifestations are related to muscle dysfunction. The disease often presents as a ‘myopathy’ with symptoms and signs of muscle abnormalities. The heart muscle can also be involved. Muscle biopsy usually shows the characteristic glycogen accumulation within vacuoles. The severity and rate of progression of the disorder vary widely from individuals with severe disease presenting in infancy to those with a more gradual adult onset. In general, these clinical differences reflect different mutations in the same gene, but a direct correlation is not always possible. Blood glucose levels are not usually affected and liver enlargement is not common. Treatment is now approached by enzyme replacement using alglucosidase-alfa (Myozyme®).

Type III (Cord/Forbes)

The absence or dysfunction of the debranching enzyme leads to the accumulation of glycogen with an abnormal structure

as noted above. This 'limit dextran' represents the product of phosphorolysis up to the limits imposed by the branches. Such products are bulky with short outer branches.

As infants, affected individuals resemble those with type I GSD – they have hypoglycemia and liver enlargement. In general, the manifestations become less severe with age and individuals can survive to adulthood. Because both liver and muscle forms of the enzyme exist, rare individuals can show selective organ involvement. Early reports suggest that there may be rare individuals who lack either of the two functions of this bifunctional enzyme, but no recent studies are available.

Treatment is generally the same as for individuals with type I GSD, although the requirements are generally less stringent. Liver transplantation has also been used, but does not affect muscle dysfunction.

Type IV (Andersen)

Consistent with the structure and synthesis of mature glycogen, defective formation of branches leads to very long polymers and bulky particles. The resulting molecules resemble amylopectin and the manifestations are related to their accumulation in the liver with attendant dysfunction of metabolic activity and, particularly, derangement of liver architecture known as cirrhosis. Complications of cirrhosis ensue in many individuals leading to liver failure and death. Since these polymers are degradable, low blood glucose complications are generally not found. A rare variety appears to largely involve muscle. Liver transplantation has been successful in selected individuals.

Type V (McArdle)

Types V and VI represent the consequences of organ-specific dysfunction of phosphorylase, the primary enzyme for glycogen degradation. Type V, the muscle-specific form, is recognized by intolerance to prolonged muscle activity. In most individuals, quiet activities are managed well and no symptoms develop, but rapid exercise can cause severe, acute muscle pain and the loss of muscle tissue integrity. Muscle cramps after exercise are common and may progress to muscle destruction – rhabdomyolysis. Usually, symptoms develop in adolescence or young adulthood. Because muscle glycogen is the source of energy for acute contraction, the manifestations of type V GSD often are related to the intensity of the exercise.

Because of the reduced availability of glucose for muscle contraction, blood levels of lactic acid fail to rise after ischemic exercise. This can be tested by measuring lactic acid levels in the forearm following repeated exercise. Although useful, these measurements are not specific for type V and can be found in other disorders affecting these pathways. Another useful correlative test is ^{31}P MRI, which shows a lack of the expected decrease in intracellular pH with exercise (as well as an exaggerated reduction in phosphocreatine).

The phosphorylase found in muscle is unique to it, and thus its mutations do not directly affect other tissues. Ingesting sucrose prior to exercise may be helpful, but the most effective treatment is avoidance of intense exercise; this often can lead to a relatively stable clinical course.

Type VI (Hers)

The mutations in this disorder are the hepatic counterpart of those in type V GSD. In general, the manifestations are milder than in individuals with type I(a,b), but poor blood glucose control and liver enlargement due to glycogen storage are observed. Muscle problems are not encountered (cf. type V). The prognosis is usually good if control of blood glucose levels can be maintained; often this can be accomplished through diet alone.

Type VII (Tauri)

Dysfunction of the muscle form of phosphofructokinase leads to manifestations similar to those in individuals with GSD type V – exercise-related muscle pain and fatigue. However, the symptoms are generally less severe. The likely pathophysiology involves elevation of the level of glucose-6-phosphate in muscle cells leading to increased glycogen synthesis. Giving glucose to affected individuals leads to lower levels of fatty acids, which normally would serve as an important energy source for muscle during contraction. Thus, while (as noted above) administering glucose can be helpful to muscle cells in type V GSD, it can aggravate the consequences of the mutation in type VII. There is no specific treatment for this form of GSD. Avoidance of strenuous exercise (similar to the advice for individuals with type V GSD) is generally effective.

Type IXa

Disorders in this category are grouped by effects on a single function. Phosphorylase kinase is a heterotetramer (subunits α , β , γ , and δ). Of several different disorders, the most frequently recognized is the X-linked form, affecting only males (it is the only X-linked form of GSD). Several mutations have been identified in the α -subunit of phosphorylase b kinase. Two α -subunits (for muscle and liver, respectively) are found at nonadjacent loci on the X-chromosome, but only the hepatic form has been associated with this disorder (GSD IXa).

These individuals usually show moderate liver enlargement and liver-function abnormalities early in life; growth is often delayed. Problems due to low blood sugar levels are not common. In general, the manifestations become less prominent with age. Treatment is not generally required once the diagnosis has been recognized and adults generally manage well.

Type IXb

Defects in the β subunit of phosphorylase kinase lead to clinical manifestations similar to those in α -subunit mutation patients. However, muscle weakness may be found; and both males and females can be affected, consistent with the genetic location for the gene. Treatment is not usually needed.

Type IXc

Mutations in the testis/liver isoform of the γ -subunit of phosphorylase kinase also affect both sexes. Although most clinical

manifestations are similar to those seen in GSD IXa, hepatic cirrhosis may develop in these individuals.

Summary

Although GSDs are rare, as a group they have led to the understanding of many aspects of glycogen metabolism. Clinical difficulties develop based on the site of the underlying defect(s). The care of affected individuals emphasizes controlling blood glucose levels and minimizing organ damage that can result from inadequate glucose mobilization and/or glycogen accumulation. Liver transplantation and gene-product administration are treatment options for selected patients.

Glossary

Adenomatous polyposis coli (APC) A large protein that is frequently mutated in colorectal cancer, which is a component of the β -catenin destruction complex.

Glycogen synthase (GS) The rate-limiting enzyme of glycogen deposition that is inhibited by phosphorylation.

Nuclear factor of activated T cells (NF-AT) A family of transcription factors first characterized in T lymphocytes as a critical regulator of cytokine expression, including interleukin-2.

Nuclear factor of κ B (NF- κ B) An important transcription that binds specific sequences in DNA and plays roles in regulating inflammatory responses and in deciding whether a cell will live or die following stress.

Protein kinase An enzyme that catalyzes the transfer of phosphate from adenosine triphosphate to the serine, threonine, or tyrosine residues.

Wnt An evolutionarily conserved family of extracellular proteins that regulate developmental processes by binding to a specific receptor (Frizzled) and initiating a cascade of events within cells that includes the accumulation of β -catenin.

GSK-3 Genes and Proteins

Mammalian genomes harbor two genes that encode for three variants of glycogen synthase kinase-3 (GSK-3) (Figure 1). The GSK-3 α gene is located on human chromosome 19q13.2 (mouse chromosome 7) and codes for a 51-kDa protein. The GSK-3 β gene is located on human chromosome 3q13.33 (mouse chromosome 16) and expresses a 47-kDa protein that is >95% identical to GSK-3 α in the kinase catalytic domain. Through differential splicing, the GSK-3 β gene also encodes a variant termed β' in which a 39-bp exon is included, adding a 13-amino-acid loop within the catalytic core. Both genes are widely expressed in all mammalian tissues and the crystal structure of GSK-3 β has been solved. GSK-3 α and GSK-3 β differ considerably in their noncatalytic regions (shown in green in Figure 1).

GSK-3 is an ancient and conserved protein, with clear homologs in all eukaryotes. Much of the functional knowledge of the enzyme has been derived from analysis in genetically tractable organisms such as fruit flies, slime mold, and yeast. With the recent characterization of mouse conventional and conditional knockouts of the two GSK-3 genes, the role of this protein kinase in mammals has been significantly advanced.

Regulation of GSK-3

Protein kinases are typically subject to intricate modes of regulation – in most cases, their activity is not expressed unless a specific signal is received by a cell. GSK-3 displays the rare behavior of being highly active in the absence of cellular stimulation. Thus, in resting cells, the protein phosphorylates a large catalog of substrate proteins. Upon stimulation by several classes of growth factors, hormones, and other agents, GSK-3 activity is repressed or diverted, relieving phosphorylation of its targets. In general, the functions of substrate proteins of GSK-3 are inhibited by phosphorylation. Hence, GSK-3 acts like a general cellular brake to suppress the activity of its

many targets (see Figure 2). This strategy allows cells to quickly respond to stimuli by activating specific cohorts of pre-existing proteins through deactivation of just one enzyme. This also raises the important question of signaling specificity. If multiple signals target the same regulatory molecule, how does a cell discriminate between signals? The answer to this conundrum lies in fractionation of GSK-3 into differentially controlled pools. Notably, however, genetic inactivation and small molecule inhibitors of this protein kinase short-circuit this organizational sequestration and cause indiscriminate inactivation.

There are two primary mechanisms by which GSK-3 activity is regulated. Both GSK-3 α and β are inhibited by phosphorylation of a serine residue located within the N-terminal regulatory domain (serine 21 in the α -isoform and serine 9 in β). Several protein kinases phosphorylate these regulatory residues including protein kinase B (PKB)/Akt, cyclic adenosine monophosphate (AMP)-dependent protein kinase, p70 S6 kinase, and several protein kinase C isoforms. As a consequence, a wide variety of stimuli result in GSK-3 inactivation including those that induce receptor-tyrosine kinases, such as the insulin receptor, which activate phosphatidylinositol 3' kinase (which activates PKB/Akt), and agonists of G-protein-coupled receptors that result in elevated cyclic AMP (Figure 2).

GSK-3 activity is also modulated by the Wnt signaling pathway by a completely distinct and insulated mechanism (Figure 3). Wnt-mediated inhibition of GSK-3 specifically targets a small and select fraction of GSK-3 molecules that are associated with the Axin/adenomatous polyposis coli (APC) destruction complex. In resting cells, this high-molecular-mass complex acts as an efficient machine to tag cytoplasmic β -catenin, an oncoprotein associated with colon cancer and other neoplasms, for proteosomal degradation. In the absence of a Wnt signal, cytoplasmic β -catenin molecules are captured by a scaffolding protein termed 'Axin1'. Axin1 also sequesters a portion of GSK-3 molecules within the cell – likely only 5–10% of the total GSK-3. Although GSK-3 cannot phosphorylate soluble β -catenin, when both molecules are coordinately bound to Axin1, GSK-3 efficiently targets three residues (Ser33,

Figure 1 Domain and intron/exon structure of the two mouse GSK-3 genes. The regulatory phosphorylation sites are indicated. Variable regions are shown in green and the kinase domain in yellow.

Figure 2 Simplified map of the regulation of GSK-3 by growth factors and mitogens. Several GSK-3 target proteins are indicated to represent the different classes of molecules regulated by GSK-3.

Ser37, and Thr41) within the amino-terminal domain of β -catenin. This phosphorylation is ordered (41 to 37 to 33) and requires phosphorylation of Ser45 by casein kinase 1, although the level of phosphorylated Ser45 does not appear to be regulated and is not limiting. The N-terminal pair of these phosphorylated residues (Ser33 and Ser37) form a recognition motif for specific E3 ligases such as β -TrCP that conjugate ubiquitin to β -catenin, which signals its rapid destruction by the 26S proteasome.

In the presence of certain members of the Wnt family (which comprises 15 secreted glycoproteins), a signaling cascade is initiated through engagement of the Frizzled class of receptors and the low-density lipoprotein receptor-related protein-5/6 (LRP5/6) coreceptors. Ligand binding recruits an adaptor molecule termed 'dishevelled' (there are three mammalian dishevelled proteins) that promotes re-organization of the Axin/APC destruction complex, whereby LRP5/6 becomes phosphorylated by GSK-3 and Casein kinase-1, which creates a high-affinity binding site for Axin. This disrupts the functioning of the Axin/APC complex allowing β -catenin to escape phosphorylation by GSK-3. As a consequence, β -catenin

accumulates within the cytoplasm, translocates to the nucleus, binds to the T-cell transcription factor (TCF)/lymphocyte enhancer-binding factor (LEF) family of DNA-binding proteins and modulates expression of genes such as *cyclin D*, *c-myc*, and *axin2*. The protein product of this latter gene facilitates reassembly of the APC destruction complex and thereby shuts down Wnt signaling by restoring degradation of β -catenin. Mutations in APC or the phosphorylation domain of β -catenin result in highly elevated levels of β -catenin within cells and loss of growth control. Indeed, mutations in one of these two molecules are found in the majority of colon cancers.

Although two distinct pathways converge to inhibit the same signaling molecule, GSK-3, the cellular consequences of inactivation are specific to the signal. Thus, inactivation of GSK-3 via N-terminal phosphorylation of serine 21/9 does not result in stabilization of β -catenin; nor does Wnt signaling impact metabolic targets that are regulated by insulin or growth factors. The precise mechanisms underlying the specificity determinants remain unclear but are likely related to sequestration of a subset of GSK-3 molecules in the APC/Axin complex, effectively shielding this subset from external

Figure 3 Regulation of GSK-3 by the Wnt and Hedgehog signaling proteins. The resting and stimulated states of these pathways are indicated for comparison.

regulation. Moreover, N-terminal phosphorylation of GSK-3 results in only partial inhibition (~50%) which is likely insufficient to impact the highly efficient phosphorylation/degradation of β -catenin, but has significant mass action consequences in metabolism.

Both isoforms of GSK-3 are also phosphorylated on a tyrosine residue within the P-loop of the catalytic center. Although phosphorylation of this site is required for full activity, the level of phosphorylation does not appear to be regulated (unlike, e.g., the analogous tyrosine residues in mitogen-activated protein (MAP) kinases). A protein-tyrosine kinase has been identified (Zak1) that targets the tyrosine in slime mold. However, in mammals, the residue is modified by autophosphorylation during the initial translational process, similar to a process initially observed in dual specificity tyrosine phosphorylation regulated kinase (DYRK) protein kinases.

As an aside, although Wnt signaling results in a decrease of GSK-3 phosphorylation of β -catenin and this underpins activation of this pathway, Wnt actually increases GSK-3 phosphorylation of LRP5/6. Hence, Wnt does not inactivate GSK-3 *per se*, rather, it uses a bait-and-switch mechanism to divert the action of GSK-3 away from β -catenin.

A Primer on GSK-3 Substrates

Many (but not all) of the proteins that are phosphorylated by GSK-3 require prior phosphorylation by a distinct protein kinase (Table 1). The primary substrate recognition sequence of GSK-3 is Ser/Thr-X-X-Ser/Thr-phosphate, where X is any amino acid but with a preference for proline. In theory, this prerequisite for prior phosphorylation provides an additional

Table 1 Known GSK-3 substrate proteins classified by function

<i>Metabolism</i>	<i>Structural</i>	<i>Transcriptional</i>
Amyloid precursor protein	Adenomatous polyposis coli	cJun (AP-1)
ATP-citrate lyase	CRMP2/4	β -Catenin
Axin	Dynamin-like protein	C/EBP
CDGAP	Dystrophin	CREB
Cubitus interruptus	Kinesin Light Chain	DF3/MUC
Cyclin D1, E	MAP 1B, 2, 2C	GATA4

R11 subunit of PKA		TCF
Tuberous sclerosis 2		vHL

regulatory step but, in practice, many of the primed phosphorylation sites are unregulated and fully phosphorylated. Instead, the priming mechanism appears to allow a distinct form of regulatory control at the level of GSK-3 itself. The crystal structure of GSK-3 β revealed the presence of several positively charged residues including a critical arginine (Arg 96) within the substrate-binding domain in a location that would permit

interaction with the priming phosphorylated amino acid in the incoming substrate. In other words, the primed phospho-amino acid is an important contributor to substrate binding. However, when GSK-3 is phosphorylated within its N-terminal domain (serine 21 or 9 in GSK-3 α or β , respectively), this phosphorylated serine competes for the primed phosphorylation-site-docking motif and when bound sterically occludes the active site. Hence, the protein kinase activity is effectively inhibited.

Substrates that require priming include glycogen synthase, cyclic AMP response element-binding protein (CREB), inhibitor-2, cyclin E, Tau, and β -catenin. Enzymes that catalyze priming of GSK-3 substrates include casein kinases 1 and 2, DYRK, and cyclic-AMP-dependent protein kinase. As can be seen from (Table 1), many GSK-3 substrates are transcriptional regulators. These include nuclear factor of activated T cells (NF-AT), a key regulator of cytokine expression. GSK-3 phosphorylation of NF-AT causes its transport from the nucleus, effectively inactivating the protein. This is reversed by the phosphatase, calcineurin, which is the target of the immunosuppressive agent, cyclosporine. GSK-3 is also implicated in other immune responses such that small molecule GSK-3 inhibitors can suppress chronic inflammation in several animal models.

Physiological Functions of GSK-3

GSK-3 has been implicated in a wide variety of cellular processes and pathologies. The first genetic analysis of the protein kinase occurred in the fruit fly where mutants of the single *Drosophila melanogaster* GSK-3 gene, termed 'Zeste-White3' or 'Shaggy', were found to display a phenotype similar to continuous signaling of the Wingless pathway, the fly counterpart of the mammalian Wnt signaling system. Wnts are a family of glycoprotein ligands that signal through a canonical pathway that acts on β -catenin or through a noncanonical pathway that involves calcium and guanosine triphosphatase (GTPase) signals. The canonical pathway plays an important role in controlling the activity of the β -catenin proto-oncogene that has been found to be mutationally activated in several cancers. Since GSK-3 negatively regulates β -catenin (in addition to other onco-proteins such as the c-Jun and c-Myc transcription factors and cyclin D, a CDK activator), it is a candidate tumor-suppressor gene. However, mutations in GSK-3 have not been found in human cancers. The most likely reason is that the two mammalian isoforms of GSK-3 are encoded by distinct genes and many (but not all) of their functions are redundant. Thus, both alleles of both genes would have to be inactivated to effect complete disruption of function – an unlikely event given that loss of the first would confer no selective advantage. A second possibility is that mutational inactivation of GSK-3 is incompatible with basic cellular properties that are requisite for tumor growth, such as proliferation. However, embryonic stem cells engineered to lack both copies of both GSK-3 genes are viable and proliferate normally.

A developmental pathway that often works in concert with the Wnt pathway is the Hedgehog pathway. Hedgehog, like Wnt, is a secreted factor but instead of targeting β -catenin, Hedgehog signaling prevents the cleavage of a protein termed Gli in mammals and Cubitus interruptus (Ci) in

flies (Figure 3). In resting cells, Ci is processed into two fragments, one of which acts as a transcriptional repressor. This cleavage requires phosphorylation of Ci by GSK-3. Upon binding of Hedgehog to its receptor, (patched) Gli cleavage is inhibited. The pathway, thus, has several parallels to Wnt signaling, although it is unclear whether GSK-3 is directly regulated by Hedgehog signaling or is, instead, a passive player that maintains low amounts of the uncleaved Ci protein under resting conditions. GSK-3 has also been implicated in Notch signaling since inactivation of the kinase results in increased amounts of the intracellular domain of Notch following Notch ligand engagement (Delta, Jagged).

Neurological Diseases

Dysregulation of GSK-3 has been implicated in neurological diseases such as Alzheimer's disease and bipolar disorder. This protein kinase is one of several that targets phosphorylation sites on the microtubule-associated protein Tau that are found to be hyperphosphorylated in insoluble structures termed 'neurofibrillary tangles'. These deposits are found in the brains of patients with Alzheimer's disease and are associated with neuronal death. Transgenic mice expressing a mutant of GSK-3 β that cannot be inhibited by N-terminal phosphorylation demonstrate higher than normal Tau phosphorylation. Activation of GSK-3 in neuronal cells has also been correlated with induction of apoptosis such that death induced by serum deprivation can be suppressed by GSK-3 inhibition.

GSK-3 is inhibited by lithium ions at concentrations (1 mM) that are therapeutically effective for the treatment of bipolar disorder. GSK-3 has also been implicated in schizophrenia. Variants in disrupted in schizophrenia 1 (DISC1) gene were identified in a Scottish family with a high incidence of this disorder. GSK-3 binds to DISC1 and this affects the functions of each protein. For example, inhibition of GSK-3 alleviates the behavioral changes associated with DISC1 mouse mutants. Inhibitors of GSK-3, therefore, have potential therapeutic value in the control of at least three neurological disorders.

Metabolism and Diabetes

Although the initial identification of GSK-3 was rooted in the study of glycogen metabolism, study of this kinase has largely focused on its roles in other processes. GSK-3 is the predominant regulator of glycogen synthase inhibition. This role has been reinforced by studies assessing the effects of GSK-3 inhibitors on glucose uptake and metabolism in response to insulin. Insulin acts to activate phosphatidylinositol 3' kinase and PKB leading to phosphorylation and inactivation of GSK-3 (Figure 2). Inhibitors of this protein kinase may, therefore, be predicted to act as insulin sensitizers. Such drugs are highly sought in the treatment of type 2 diabetes, a growing health problem as populations increase their degree of obesity and age. Small molecule inhibitors of GSK-3 have been shown to act as effective insulin sensitizers in several animal models of diabetes, reducing circulating blood glucose and enhancing glycogen deposition. In addition to negatively regulating

glycogen synthase, GSK-3 also phosphorylates and inhibits other proteins important to insulin's mechanism of action including IRS1, ATP-citrate lyase, and eIF2B. Thus, GSK-3 inhibition promotes anabolic processes such as fatty acid and protein synthesis.

One potential spoiler to the use of GSK-3 inhibitors as insulin sensitizers is the concern that chronic inhibition of this protein kinase may lead to inappropriate accumulation of β -catenin, a potential oncogene. However, cells appear to have a built-in fail-safe mechanism that normally prevents unscheduled induction of β -catenin. For example, loss of 75% of total GSK-3 activity results in virtually no increase in noncadherin-associated β -catenin. Inhibition of greater than 75% of GSK-3 activity is required for substantial stabilization in the absence of a specific signal (one of the Wnts). The reason for this is at least partially related to the relative levels of the Wnt signaling components compared to GSK-3. Axin is present at significantly lower concentrations than GSK-3 ($\alpha + \beta$). Hence, only when total GSK-3 levels decrease below that of Axin will processing of β -catenin be affected in the absence of a Wnt signal. Since most therapeutics are used at concentrations that dampen rather than eradicate activity, a therapeutic window may exist that allows tempering of aberrant GSK-3 activity without impacting stabilization of β -catenin. However, this Damocles sword will perch over the use of GSK-3 inhibitors until at least preclinical trials demonstrate no increase in tumor incidence upon chronic administration of the drugs. Given rapid progress in the development of potent and specific inhibitors of GSK-3, of which some 5000 now exist, an answer to this question should be forthcoming.

Knockout Mouse Models

Mice lacking GSK-3 β are susceptible to embryonic death due to liver failure. The defect was traced to aberrant induction of the NF- κ B transcription factor by tumor necrosis factor- α (TNF- α) in the liver that leads to hepatocyte cell death. TNF- α induced by opportunistic infection of the mother typically induces both a proapoptotic and an NF- κ B-mediated survival signal within cells. However, in the cells lacking GSK-3 β , induction of survival genes by NF- κ B was found to be suppressed, leading to dominance of the proapoptotic signal and the demise of the hepatocytes. The mechanism by which GSK-3 β influences NF- κ B is unclear, although there is evidence of both positive and negative regulation. Chemical inhibition of GSK-3 also leads to sensitization of cells to TNF- α . Of note, although the embryonic lethality of the mice lacking GSK-3 β can be rescued either by injection of anti-TNF- α antibodies or by breeding with mice that lack the 55-kDa receptor for TNF- α , the mice still die shortly after birth due to a patterning defect in the heart that resembles a human condition termed 'double-outlet right ventricle (DORV)' in which pulmonary circulation is ineffective leading to an inability to oxygenate blood via the lungs. The behaviors of GSK-3 β heterozygous mice are similar to those treated with lithium. The drug treatment leads to ~25% inhibition of total GSK-3, which is comparable to

the levels of the total kinase in the GSK-3 β heterozygous animals (since they retain GSK-3 α).

Mice lacking GSK-3 α are viable but display increased insulin sensitivity as well as behavioral differences and susceptibility to cardiomyopathy when stressed. Nonetheless, these animals exhibit a normal life span under typical conditions.

To allow examination of the role of GSK-3 β in adult animals, conditional alleles have been generated and tissue-specific inactivation of GSK-3 β (and GSK-3 α) achieved by crossing with selective Cre recombinase deleter strains. Through this methodology, selective inactivation of GSK-3 β in skeletal muscle was found to sensitize animals to insulin. Inactivation of GSK-3 β in insulin-producing β -islet cells of the pancreas has been reported to prevent insulin resistance caused by inactivation of IRS2 or haploinsufficiency of the insulin receptor. These results suggest tissue-dependent roles of the two GSK-3 isoforms, although this property is unlikely to be exploitable given that the only means to selectively inactivate either isoform is via RNA interference.

Life without GSK-3

Genetic inactivation of all four alleles of GSK-3 in embryonic stem cells results in maintenance of expression of pluripotency factors such as Nanog and Oct4 and suppression of differentiation potential. Conditional inactivation of total GSK-3 during brain development results in continued proliferation of neuronal precursors and radial glial cells and inhibits differentiation into functional neurons. These cells exhibit elevated cMyc, β -catenin, Notch, and Hedgehog signaling as might be predicted from the multiple suppressive roles of this protein kinase. These findings raise the possibility that reversible inactivation of GSK-3 may allow transient expansion of progenitor cell populations for regenerative medicine purposes.

GSL Assembly in Membrane as GSL-Enriched Microdomain

Cluster Formation by GSL-to-GSL *cis*-Interaction

Ceramide, the lipid moiety of glycosphingolipids (GSLs), has aminoacyl (*N*-acyl) residue and hydroxyl group that act as hydrogen bond donors, whereas glycerides and glycerophospholipids have only *O*-acyl group that act as hydrogen bond acceptor. In addition, GSLs have a number of hydroxyl groups and *N*-acyl residues at the sugar moiety, that may provide a much stronger hydrogen bond donor (Figure 1(a)). At the plane of lipid bilayer, the presence of sphingolipids and GSLs therefore provides higher and stronger *cis*-interaction (i.e., GSL-to-GSL side-by-side interaction). Glycerides and glycerophospholipids in the same lipid bilayer plane, although they constitute the major lipid components, show much weaker *cis*-interaction. By a similar mechanism, glycoproteins show strong *cis*-interaction, possibly through their hydrogen bonds, to form clusters separable from GSL clusters. Thus, GSLs and glycoproteins are clustered to form independent patches or islands separated from the sea of glycerophospholipids on the cell surface, as shown in Figure 1(b). Sphingomyelin interacts with cholesterol but is separated from glycerophospholipids in gel state, as evidenced by electron spin resonance and infrared spectroscopy. GSL clusters occur in the absence of cholesterol.

Association of Clustered GSLs with Lipophilic Signal Transducers and Proteolipids: Assembly of Glycosynapse

Clustered GSLs in cell membranes can be separated as insoluble low-density membrane by homogenization in high-salt, or in lysis buffer containing neutral detergent, followed by density-gradient ultracentrifugation. The GSL-enriched buoyant fraction contains >95% of GSLs originally present in cells, but <1% of total cellular protein. The proteins found in this fraction, from many cell types, are cSrc, other Src family kinases, and small G proteins (Ras, RhoA, RAC), which contain

long-chain aliphatic acyl groups and are closely associated with GSLs. In addition, the fraction has proteolipid proteins and tetraspanins, which are also closely associated with GSLs and signal transducers. Molecular assembly of these components in microdomain forms a functional unit in membrane essential for cell adhesion with concurrent signal transduction; the unit is collectively termed as 'glycosynapse'.

Cell Adhesion through Clustered GSLs

Two types of GSL-dependent cell adhesion processes can be considered.

1. GSL cluster is recognized by or bound to complementary GSL cluster expressed on counterpart cell-surface glycosynapse (i.e., GSL-to-GSL *trans*-interaction). Such interaction takes place through specific complementary structures. The binding between carbohydrate moieties of GSLs is catalyzed, in many cases, by Ca²⁺. There is a steadily increasing number of examples of such complementary GSL pairs, providing the basis of GSL-dependent adhesion. A model of such interaction involving single molecules of Gb4 and nLc $_4$, as a basis of cell adhesion, is shown in Figures 2(a)–2(c). In reality, however, GSLs are not present as single molecules, but are clustered on membrane. Cell adhesion occurs through such GSL clusters in association with signal transducers (glycosynapse), to activate or inhibit signaling. A model is shown in Figure 3.
2. GSL cluster, particularly ganglioside cluster, is bound to ganglioside-binding lectin (siglec) such as siglec-4 or -7. Alternatively, GSL having β Gal residue (e.g., GM1) is recognized by galectin, or GSL having SLe x or SLe a residue is recognized by E-selectin.

Processes 1 and 2 are shown schematically in Figure 4. In either process, structure of GSLs is the target of cell adhesion, recognized by complementary GSL (Figure 4(a)) or by specific binding protein (Figure 4(b)), which triggers activation or inhibition of signal transducers.

Figure 1 Clustering of glycosphingolipids and glycoproteins on membrane due to *cis*-interaction. (a) Contrasting properties of GSLs and glycerophospholipids in ability for hydrogen bond formation. GSLs are both hydrogen bond donors and acceptors (indicated respectively by $\cdots\text{H}-\text{O}$ and $\text{O}=\text{C}$), whereas glycerophospholipids only accept hydrogen bond, due to absence of hydroxyl group (OH). (b) Clustering is visualized by scanning electron microscopy following freeze-fracture technique: glycoprotein (Gph) clustering, and globoside (Gb4) clustering on erythrocyte membrane (in 1), GM1 clustering on dipalmitoyl phosphatidylcholine liposome surface (in 2). Cell-surface GSL clustering is also observed by transmission electron microscopy using specific antibody-gold sol conjugates: GM3 clustering on T-lymphocyte surface (in 3), and polysialoganglioside clustering in neuronal cells (in 4).

Figure 2 *trans*-Interaction of GSLs as a basis of glycolipid-dependent cell adhesion. (a) Minimum-energy conformational model of Gb4 and nLc₄. Note that axis of carbohydrate is perpendicular to that of sphingosine and fatty acid (ceramide). (b) Gb4 on the surface of one cell and nLc₄ on the surface of counterpart cell have complementary surface profile. (c) Gb4 and nLc₄ adhere to each other, by carbohydrate-to-carbohydrate interaction, on the basis of cell adhesion.

Figure 3 Model of GSL-based glycosynapse, and GSL-dependent adhesion through carbohydrate-to-carbohydrate interaction. (a) Clustered GSLs on the surface membrane of one cell are bound to a cluster of another type of GSL on surface membrane of counterpart cell, through *trans*-interaction of GSLs as in Figure 2. (b) Such adhesion induces change (activation or inhibition) of signal transducers (TDa and TDb) to send signals (a and b). In some cases, this process is synergistic with another adhesion system, such as integrin receptor (I) and its binding counterpart (R, e.g., ICAM1), or other type of carbohydrate-dependent receptor (S, e.g., CD44).

Types of Cell Adhesion Mediated by GSL-to-GSL Interaction

Mouse Melanoma B16 Cell Adhesion to Mouse Endothelial Cells through GM3-to-LacCer or GM3-to-Gg3Cer Interaction

B16 cells are characterized by predominance of GM3 ganglioside. Their adhesion to mouse or human endothelial cells

(ECs) is based on interaction of GM3 (on melanoma cells) with LacCer or Gg3Cer (on ECs). LacCer is present on essentially all types of ECs, whereas Gg3Cer has a more restricted distribution on lung microvascular ECs, where metastasis may occur preferentially. The degree of this GM3-dependent adhesion is closely correlated with the metastatic and invasive

Figure 4 Two types of GSL clusters in glycosynapse function in GSL-dependent adhesion. Adhesion of cell a to cell b occurs via adhesion processes 1 and 2. (a) Process 1 is based on GSL clusters associated directly with signal transducers (TDs), and stabilized by proteolipids (PLs). Adhesion proceeds through interfacing of the two glycosynapses, and carbohydrate-to-carbohydrate interaction, and concurrent activation or inhibition of signal transducers. (b) Process 2 is based on GSL clusters and their binding protein (BP). Through interfacing of the two glycosynapses, GSLs are bound to BP, whereby TD is activated or inhibited.

potential of B16 cells, based on the following observations: (1) *in vitro* GM3-dependent adhesion was inhibited by liposomes containing GM3, LacCer, or Gg3Cer; (2) *in vivo* metastatic potential of B16 cells in terms of lung colonization was inhibited by administration of GM3- or Gg3Cer-liposomes; and (3) enhancement of B16 cell motility and invasiveness following GM3-dependent adhesion was indicated by activation of cSrc, RhoA, and FAK at glycosynapse. GM3-to-Gg3Cer and -LacCer interactions were well studied recently by surface plasmon resonance spectroscopy.

F9 Cell Autoaggregation through Le^x-to-Le^x Interaction

Mouse embryonal carcinoma F9 cells show strong autoaggregation, simulating morula-stage preimplantation embryo. Both F9 cell autoaggregation and compaction of morula are inhibited by a trivalent Le^x-lysyllysine conjugate. The molecular mechanism of Le^x-dependent autoaggregation was found to be Le^x-to-Le^x interaction in the presence of Ca²⁺. The process was recently well elucidated by molecular force microscopy and by surface plasmon resonance spectroscopy.

Human Embryonal Carcinoma Autoaggregation through Gb4-to-nLc₄ or Gb4-to-Gb5 Interaction

Gb4, Gb5, and nLc₄ are highly expressed, in addition to Le^x, in mouse preimplantation embryo. Expression of Gb5 is much higher than that of Le^x in human embryonal carcinoma and in primate preimplantation embryo, although the expression

status of these GSLs and carbohydrate antigens in human embryo has not been studied for ethical reasons. Autoaggregation of human embryonal carcinoma, which may mimic the compaction process of human embryo, is mediated by Gb4-to-nLc₄ or Gb4-to-Gb5 interaction (Gb4-dependent adhesion). These GSLs are closely associated with cSrc, RhoA, and Ras in glycosynapse, and may induce differentiation following Gb4-dependent adhesion.

Rainbow Trout Sperm Binding to Egg Mediated by (KDN)GM3 Interaction with Gg3-Like Epitope

A novel deaminated analog of sialic acid, 2-keto-3-deoxy-D-glycero-D-galacto-nononic acid (KDN), is found in fish egg and sperm. The head of rainbow trout sperm has a high content of (KDN)GM3, as indicated by reactivity with specific anti-(KDN)GM3 mAb kdn3G, and binds strongly to plates coated with Gg3, but not other GSLs. This binding is inhibited by kdn3G and by anti-Gg3 mAb 2D4. Vitelline envelope membrane isolated from rainbow trout egg has a glycoconjugate containing Gg3-like epitope, defined by antibody 2D4. Immunoelectron microscopy revealed that the Gg3-like epitope is highly expressed in exposed second layer of vitelline envelope surrounding the micropyle, a narrow channel through which a sperm enters the egg cell. Thus, interaction of (KDN)GM3 at sperm head with Gg3-like epitope surrounding the micropyle is a crucial event in the process of rainbow trout fertilization.

Types of Cell Adhesion Mediated by Interaction of GSL with GSL-Binding Protein

Neuronal Axon Binding to Myelin through Interaction of Ganglioside with Siglec-4

Neuronal cell membranes are characterized by the presence of ganglio-series gangliosides. Gangliosides expressed at neuronal cell axons interact with myelinating glial cells through myelin-associated glycoprotein (MAG), which was known previously as sialic acid-binding protein siglec4. GD1a and GT1b, which have sialyl $\alpha 2 \rightarrow 3$ Gal terminal residue, are specific functional ligands of MAG that inhibit nerve regeneration and neurite formation. Inhibition of ganglioside synthesis by P4, or blocking of ganglioside interaction with MAG by anti-ganglioside IgG antibodies, reversed the MAG-dependent inhibitory effect on neurite formation.

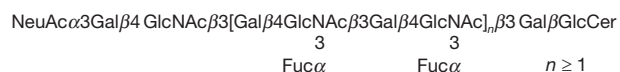

Aggregation of Renal Cell Carcinoma TOS1 Cells with Peripheral Blood Mononuclear Cells through Interaction of Disialoganglioside with Siglec-7

Renal cell carcinoma (RCC) has high metastatic potential to lung, and the degree of this potential is correlated with RCC expression of disialogangliosides, which are ligands of sialic acid-binding protein siglec-7, the major siglec expressed in peripheral blood mononuclear cells (PBMCs). These disialogangliosides expressed in RCC were identified as disialyl-Lc₄ (defined by mAb FH9), GalNAc-disialyl-Lc₄ (defined by mAb RM2), disialyl-Gb5 (defined by mAb 5F3), and GD3 (defined

by mAb R24). RCC cell line TOS1 is characterized by expression of disialyl-Lc₄, GalNAc-disialyl-Lc₄, and GD3, and interacts with siglec-7 on the surface of PBMC, causing aggregation of TOS1 cells with PBMCs. Large aggregates of this type may result in microembolisms that initiate metastasis, particularly in lung.

Adhesion of Neutrophils or Myelogenous Leukemia HL60 Cells to E-Selectin through Fucosyl-Poly-LacNAc Ganglioside (Myeloglycan)

Sialyl-Le^x (SLe^x) has been regarded as the major ligand of human neutrophils, or myelocytic, or monocytic leukemia cell lines (e.g., HL60 and U937) that interact with E-selectin expressed on ECs. Extensive studies on human neutrophils and HL60 cells indicated that SLe^x epitope is absent from GSLs and gangliosides of these cells. Instead, E-selectin-binding epitopes were identified as poly-LacNAc with multiple $\alpha 1 \rightarrow 3$ fucosylation and terminal $\alpha 2 \rightarrow 3$ sialylation:

These GSLs display strong E-selectin-dependent adhesion, particularly under dynamic flow conditions, and are collectively termed 'myeloglycan'.

Human Neuroblastoma Adhesion through GM1-to-Galectin-1 Interaction

Human neuroblastoma expresses ganglio-series gangliosides and galectin-1. Neuroblastoma cell contact activates endogenous sialidase, which causes conversion of GD1a, GD1b, GT1b, etc., to GM1, and consequent accumulation of GM1. GM1 is one of the ganglio-series gangliosides having terminal

β Gal residue that is recognized by galectin-1; therefore, GM1 at the neuroblastoma cell surface promotes cell-to-cell adhesion. Galectin-mediated cell adhesion has been proposed, but the target carbohydrate was identified as glycoprotein, and little attention has been paid to GSLs.

Glossary

Cancer Unlike normal tissue or a benign tumor, cancer cells exhibit the property of invasion of other organs of the body.

Hypoxia Condition in which the oxygen content of a tissue is so low that it limits electron transport activity by mitochondria.

Na⁺,K⁺-ATPase Enzyme complex present in the plasma membrane of all cells that utilizes the energy provided by adenosine triphosphate (ATP) hydrolysis to drive the transport of Na⁺ out and K⁺ into the cells.

Oxidation–reduction reactions Reaction in which one compound gets oxidized (loses electrons) and another compound gets reduced (gains electrons).

PET imaging A technique for creating an image of a tissue that relies upon the use of positron emission tomography (PET) to measure a signal produced by a short-lived radionuclide such as ¹⁸F-fluorodeoxyglucose.

Reactive oxygen species Small highly reactive oxygen-containing compounds that include the superoxide anion (O₂[−]) and hydrogen peroxide (H₂O₂). At low concentrations, they play important roles in signal transduction. At high concentrations, they damage cells and induce a condition called oxidative stress.

Role of Glycolysis

Adenosine Triphosphate Production

In the absence of either oxygen or mitochondria, glycolysis operates as a self-contained pathway with lactate as its end product (**Figure 1(a)**). Energy released by exergonic reactions is captured with the formation of two molecules of adenosine triphosphate (ATP) from two molecules of adenosine diphosphate (ADP) and inorganic phosphate (Pi):

Production of ATP by this overall sum equation for the pathway is the most important function of glycolysis. Some cells entirely depend on the ATP produced by glycolysis. For example, mature red blood cells obtain all of their ATP from glycolysis because they lack mitochondria, the oxygen-consuming organelles responsible for production of practically all of the ATP in most cells. Uninterrupted production of ATP is required for proper function and survival of all cells. The simplest of all cells in the body, red blood cells, still require the continuous operation of the glycolytic pathway to produce ATP to power their Na⁺,K⁺-ATPase and other energy-requiring processes.

Preparatory Pathway for Glucose Oxidation

When oxygen is available and mitochondria are present, glucose is completely oxidized to carbon dioxide and water (**Figure 1(b)**) by the sum reaction:

Under these conditions, glycolysis sets the stage for the complete oxidation of glucose, a process that produces 16 times more ATP per glucose molecule than anaerobic glycolysis. In the absence of either oxygen or mitochondria, glycolysis yields two molecules of pyruvate that must be reduced to lactate for glycolysis to proceed (**Figure 1(a)**). When oxygen

is present, pyruvate is taken up by mitochondria and the entire molecule is oxidized to carbon dioxide and water by the sequential actions of the pyruvate dehydrogenase complex, citric acid cycle, and the electron transport chain (**Figure 1(b)**).

Because mitochondria are present in most cells and there is continuous supply of oxygen from the blood, virtually every tissue of the body uses glycolysis as a preparatory pathway, which provides them with much greater amounts of ATP from each glucose molecule than anaerobic glycolysis. The human brain, for example, completely oxidizes about 120 g of glucose each day, all via pyruvate molecules produced from glucose by glycolysis. Lactate is present in the brain, but the amount is small and none is released into the blood because the brain is well oxygenated and mitochondria are abundant.

Three Stages of the Glycolytic Pathway

Conversion of glucose to lactate takes place in three stages in the cell cytoplasm (**Figure 2**).

Priming Stage

The first three reactions of the pathway prime the glucose molecule for use by subsequent enzymes (see **Figure 2**). ATP molecules are invested in the reactions catalyzed by hexokinase and 6-phosphofructo-1-kinase. Phosphorylation traps glucose inside the cell and sets the stage for subsequent cleavage of the glucose into two three-carbon fragments. The priming stage reactions sum up to be simply

Splitting Stage

Fructose 1,6-bisphosphate undergoes cleavage by aldolase between carbons 3 and 4 in the first step of the splitting

Figure 1 Overviews of glycolysis: (a) lactate is the product of glycolysis in the absence of oxygen and (b) glycolysis serves as a preparatory pathway for the complete oxidation of glucose in the presence of oxygen.

stage. Dihydroxyacetone phosphate and glyceraldehyde 3-phosphate, known collectively as triose phosphates, are produced by an aldol cleavage of fructose 1,6-bisphosphate. Inter-conversion of the triose phosphates by an isomerase completes the splitting stage, which sums up to be

Energy-Trapping Stage

Six enzymes are required to capture the energy made available in this stage. All of the ATP produced by glycolysis is generated by the reactions catalyzed by 3-phosphoglycerate kinase and pyruvate kinase in this stage. Since two glyceraldehyde 3-phosphate molecules are converted to two lactate molecules, a total of four ATPs is produced in this stage, which sums up to be

The sum of the three stages yields the overall equation for anaerobic glycolysis in which one molecule of glucose is converted to two molecules of lactate with the production of two molecules of ATP:

Anaerobic Glycolysis Is a Type of Fermentation

Fermentations are pathways that (1) produce ATP, (2) do not involve oxygen, (3) involve an intermediate that becomes

oxidized, and (4) involve an intermediate that becomes reduced. That ATP is produced and oxygen is not required can be seen from the overall balanced equation for glycolysis:

That an intermediate becomes oxidized and another reduced is not shown by this equation. However, during the first reaction of the energy-trapping stage of glycolysis (**Figure 2**), the aldehyde group ($-\text{CHO}$) of glyceraldehyde 3-phosphate is oxidized to a carboxylic acid ($-\text{CO}_2^-$) and then phosphorylated to give a mixed anhydride of a carboxylic acid and phosphoric acid (1,3-bisphosphoglycerate):

In the last reaction of the energy-trapping stage of glycolysis (**Figure 2**), the α -keto group of pyruvate is reduced to give the α -hydroxyl group of lactate:

NAD^+ serves as a bridge compound for these reactions (**Figure 3**), accepting two electrons and one H^+ to become NADH during the oxidation of the aldehyde group of glyceraldehyde 3-phosphate and subsequently donating two electrons and one H^+ when it

Figure 2 The three stages of the glycolytic pathway: priming, splitting, and energy trapping. Glycolytic intermediates: G-6-P, glucose 6-phosphate; F-6-P, fructose 6-phosphate; F-1,6-BP, fructose 1, 6-bisphosphate; G-3-P, glyceraldehyde 3-phosphate; DHAP, dihydroxyacetone phosphate; 1,3-BPG, 1,3-bisphosphoglycerate; 3-PG, 3-phosphoglycerate; 2-PG, 2-phosphoglycerate; PEP, phosphoenolpyruvate. Glycolytic enzymes: GPI, glucose phosphate isomerase; TPI, triose phosphate isomerase; G3PDH, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; PGM, phosphoglycerate mutase.

Figure 3 NAD^+ serves as a bridge molecule to couple the oxidation of glyceraldehyde 3-phosphate to the reduction of pyruvate during anaerobic glycolysis.

returns to being NAD^+ during the reduction of the α -keto group of pyruvate. The result is a perfect balance between the production of NADH in an oxidation step of glycolysis and its utilization in a reduction step of glycolysis. Anaerobic glycolysis is therefore a type of fermentation.

Control of Glycolysis

The rate at which ATP is hydrolyzed back to ADP and P_i by energy-requiring reactions is a major determinant of flux through the glycolytic pathway. In other words, ATP turnover caused by energy required to perform the work being done by a cell greatly affects the rate of glycolysis. The presence or absence of oxygen also has a profound effect upon the rate of glycolysis.

ATP Turnover

Two molecules of ATP are produced for each molecule of glucose utilized by glycolysis. However, for glycolysis to continue unabated the ATP produced by glycolysis must be continuously hydrolyzed back to ADP and P_i . This is because the amount of ADP present in the cells is quite small relative to the large amount of glucose that is utilized to meet the energy needs of cells. Glycolysis can therefore not proceed without hydrolyzing ATP to make ADP available for the steps catalyzed by phosphoglycerate kinase and pyruvate kinase. Hydrolysis of ATP to ADP plus P_i by energy-requiring processes is usually rate limiting for the process of glycolysis. Thus, an increase in ATP turnover caused by an increase in the amount of work being done by a cell has a profound effect upon the rate of glycolysis. For example, a marked increase in the rate of glycolysis occurs in response to strenuous exercise because of ATP hydrolysis by the contractile machinery of muscle.

Oxygen

A remarkable decrease in the rate of glycolysis occurs when cells that lack oxygen are transferred into an environment in which oxygen is abundantly available. The production of carbon dioxide starts immediately but cells use much less glucose and accumulate little or no lactate. This illustrates the Pasteur effect, which refers back to Louis Pasteur's observation (150 years ago) that oxygen inhibits the fermentation of glucose by yeast. The Pasteur effect reflects the marked difference in cellular capacity for ATP production in the presence and absence of oxygen. Relative to anaerobic glycolysis, 16 times more ATP is produced when glucose is completely oxidized to carbon dioxide and water by the combined actions of glycolytic and mitochondrial enzymes. The rate of glycolysis decreases greatly in the presence of oxygen because the ATP required to meet the energy needs of a cell can be supplied by the catabolism of much less glucose.

Lactate is not normally produced in large amounts when oxygen is available to cells. Less glucose has to be used to meet the need for ATP, which automatically means less pyruvate is produced and available for reduction to lactate by NADH. The pyruvate produced by glycolysis is also rapidly oxidized by the mitochondria, leaving less available for reduction to lactate.

by NADH. Finally, less NADH is available for the reduction of pyruvate to lactate because shuttle mechanisms operate in the presence of oxygen to transport the electrons of NADH into mitochondria (Figure 1(b)) by the net equation:

NADH generated in the mitochondria by this shuttle mechanism is oxidized by the electron transport chain, which in turn produces the energy necessary for the synthesis of ATP by oxidative phosphorylation according to the net equation:

Removal of oxygen from the environment of cells has the opposite effect. Glycolysis is greatly stimulated as evidenced by increased glucose utilization and lactate production. Anaerobic glycolysis can sometimes meet the need of cells for ATP, but often it is inadequate, in spite of an increase in its rate. Cells die when ATP is not generated fast enough to keep them viable, which is what happens in the heart during a myocardial infarct or in the brain as a consequence of a stroke. Cells that survive in an oxygen-poor environment are able to elevate their capacity for glycolysis by increasing the amounts of the glycolytic enzymes present. This in turn increases the activities of the glycolytic enzymes and therefore the capacity for ATP synthesis by glycolysis. Lack of oxygen signals an increase in the transcription of the genes that encode the glycolytic enzymes. This occurs because lack of oxygen (hypoxia) causes an increase in the amount of a protein called hypoxia-inducible factor (HIF) (Figure 4). HIF is a transcription factor that promotes transcription when it binds to a specific sequence of nucleotides in the promoter region of genes encoding glycolytic enzymes. Oxygen stimulates proteolytic degradation of HIF (Figure 4), which keeps the amount of HIF low which, in turn, keeps the amounts and therefore the activities of glycolytic enzymes low in cells. Hypoxia maximizes the amount of HIF, which greatly increases expression of the glycolytic enzymes and therefore cellular capacity for glycolysis.

Cancer

Malignant tumors make good use of glycolysis as a source of ATP. Rates of glycolysis are often faster in malignant tumors than in normal tissues. Radiologists and oncologists take advantage of this phenomenon in the diagnosis of cancer by positron emission tomography (PET) imaging with a radioactive glucose derivative. Cancer cells often accumulate larger amounts of the radioactive glucose derivative because of their greater capacity for glucose uptake and glycolysis. Surprisingly, tumors often metabolize glucose to lactate even in the presence of oxygen. This is unusual and stands in contrast to normal cells that only metabolize glucose to lactate in the absence of oxygen, as discussed previously. The conversion of glucose to lactate in the presence of oxygen is called aerobic glycolysis, to distinguish it from anaerobic glycolysis which refers to the conversion of glucose to lactate in the absence of oxygen. The high rate of aerobic glycolysis exhibited by some cancer cells is

Figure 4 Oxygen controls glycolytic enzyme expression by controlling the amount of hypoxia inducible factor (HIF), a transcription factor that regulates the transcription of genes that encode glycolytic enzymes.

called the Warburg effect, in recognition of Otto Warburg's discovery (80 years ago) that tumor cells produce lactate in the presence of oxygen. Based on this observation, Warburg championed the idea that aerobic glycolysis is the cause of cancer. Now, however, it is appreciated that upregulation of the enzymatic capacity of glycolysis occurs frequently in cancer cells because of a higher concentration of HIF, the transcription factor responsible for regulation of the transcription of genes encoding glycolytic enzymes (Figure 4). HIF is highly expressed in many tumor cells, even in the presence of oxygen, because of the mutations that have occurred in genes that either prevent (tumor suppressors) or promote (oncogenes) the development of cancer. Since tumors sometimes outgrow their blood supply and cancer cells frequently migrate into areas of the body where the oxygen concentration is low, an exceptionally high capacity for ATP production that does not require oxygen may provide cancer cells with a metabolic advantage for survival and growth. Furthermore, mitochondrial respiration is associated with the production of reactive oxygen species that can damage cellular components, inhibit growth, and cause cell death. Since the low-oxygen environment that can occur in tumors can promote the formation of reactive oxygen species by the mitochondrial electron transport chain, the increased capacity for glycolysis and reduced reliance upon oxidative metabolism may serve to protect cancer cells from being killed by increased levels of reactive oxygen species.

Lactic Acidosis

Regardless of whether anaerobic or aerobic, glycolysis produces acid if lactate is the end product of the pathway. The acid produced by glycolysis lowers the pH both inside cells where lactate is produced as well as outside where protons can diffuse. Since the pH range in which cells can function is quite narrow (pH 7.0–7.6), uncontrolled glycolysis can lead

to cell death. This is the Achilles' heel of glycolysis. Indeed, in the final analysis it is overproduction of acid and lowering of the pH by glycolysis that kills most organisms, including humans. Cells incubated under anaerobic conditions produce large amounts of acid by anaerobic glycolysis. Likewise, forcing an area of the heart to obtain all of its energy from glycolysis by occluding a coronary artery causes rapid production of large amounts of acid, which lowers the pH, activates the nerve endings, and registers as pain. That the conversion of glucose to lactate produces acid is apparent when we write the balanced overall equation for glycolysis in the following manner:

Since the empirical formula for glucose is $\text{C}_6\text{H}_{12}\text{O}_6$, and there are six carbons, 12 hydrogens, and six oxygens in the products, this equation is balanced for mass and charge. Thus, two protons are produced for every glucose molecule converted to lactate molecules by glycolysis. Since glycolysis produces two ATPs per glucose, the equation seems incomplete, and in one sense it is incomplete. Expanding the equation to include ADP, P_i , and ATP in their predominant ionization states at physiological pH yields

If this is accepted as the appropriate equation for glycolysis, balanced as it is for mass and charge, the pathway does not produce acid and therefore should have no effect on cellular pH. However, anaerobic glycolysis can clearly be shown to produce acid experimentally, and it does so because the pool size of ATP is small compared to the amount of glucose that is converted to lactate to meet the energy needs of a cell. For every glucose molecule converted to lactate, two ATP molecules have to be hydrolyzed according to the equation

Work refers to many energy-requiring processes that can only occur as a consequence of ATP hydrolysis, such as muscle contraction, Na^+, K^+ -ATPase activity. Summing up the last

two equations brings us back to the overall balanced equation that shows acid production by glycolysis:

Anaerobic glycolysis therefore produces acid. Conditions in humans that greatly increase anaerobic glycolysis because of a shortage of oxygen, for example, failure of the respiratory system or the blood circulatory system, often cause the production of more acid than can be handled by the buffering systems of the body. The consequence is lactic acidosis, a life-threatening condition. Lactic acidosis can be dealt with most effectively by re-establishing the supply of oxygen. Reinstating ATP synthesis by oxidative phosphorylation will inhibit the production of lactic acid by glycolysis and also promote the oxidation of lactate as well as the consumption of the excess acid (H^+ 's) by the sum reaction:

Glossary

BiP Classical endoplasmic reticulum-resident molecular chaperone belonging to the Hsp70 family.

Calnexin A membrane-bound endoplasmic reticulum-resident lectin that binds monoglucosylated *N*-glycans.

Calreticulin The soluble homolog of the former.

ERp57 Protein of the thioredoxin family that associates with calnexin and calreticulin and promotes proper disulfide bonding in monoglucosylated glycoproteins.

Glucosidase I A membrane-bound endoplasmic reticulum-resident glucosidase that removes the external α -(1,2)-linked Glc unit from Glc₃Man₉GlcNAc₂.

Glucosidase II A soluble endoplasmic reticulum-resident glucosidase that removes α -(1,3)-linked Glc units from Glc_{1,2}Man₇₋₉GlcNAc₂.

Glucosylation Term indicating transfer of Glc units.

Glycoproteins Proteins having covalently attached carbohydrates.

Glycosylation Generic term indicating transfer of monosaccharides or oligosaccharides.

Mannosidase I A membrane-bound, endoplasmic reticulum-resident enzyme that removes Man units from *N*-glycans.

N-glycans Glycans (or oligosaccharides) linked to Asn residues in proteins.

Quality control Mechanisms by which cells ensure that only properly folded proteins are produced by the secretory pathway.

UDP-Glc:glycoprotein glucosyltransferase A soluble, endoplasmic reticulum-resident enzyme that exclusively glucosylates glycoproteins displaying non-native conformations.

Glycoprotein Folding, Processing Reactions, and Quality Control

The term glycoprotein folding and processing reactions refer to the mechanisms by which cells ensure that only properly folded glycoproteins follow the secretory pathway. The concept of quality control of protein folding first appeared in the late 1970s and early 1980s when it was noticed that not in all cases insertion of proteins or glycoproteins in the endoplasmic reticulum (ER) lead to their expected final destination, either intracellular (e.g., the lysosomes) or secretion. Several experimental results showed that cells displayed mechanisms that ensured that only proteins in their native conformations could be produced by the secretory pathway. Those mechanisms received the collective denomination of quality control. By far, the best-studied quality control mechanism is that occurring in the ER but more recent studies revealed that it also takes place at the Golgi apparatus. The scope of this article is limited to the quality control occurring on glycoproteins in the ER.

Protein Folding in the ER

Nearly 40% of the proteins synthesized by eukaryotic cells belong to the secretory pathway. Of these, approximately 80% are *N*-glycosylated in the ER. These proteins enter the ER either post- or cotranslationally. The ER folding quality control system is adapted to handling virtually any condition that results in a protein conformation other than the native state. Accordingly, multiple scenarios of quality control arise from many ways in which proteins can fail to achieve their native conformation. All types of polypeptides inserted into the ER are subjected to

quality control, including soluble and membrane proteins (type I, II, and multispans). It applies to proteins regardless of their quaternary structure and whether they are glycosylated or not or contain intra- or intermolecular bonds. Proteins can fail the quality control due to multiple factors, such as truncations or mutations that interfere with proper folding, as well as orphan subunits of heterooligomeric complexes or homooligomers that cannot reach their proper structure. In addition, the lack of ligand binding or posttranslational modifications (signal sequence cleavage, disulfide bond formation, *N*-glycosylation, or glycosylphosphatidylinositol (GPI) anchor addition) can prevent proteins from folding correctly. Moreover, normal proteins that do not have any of the mentioned defects can also be targets of the quality control system, as protein folding is an extremely hazardous process whose efficiency heavily depends not only on particular environmental conditions but also on the amino acid primary sequence. In fact, almost never do all normal protein molecules manage to reach their proper native structure; there is always a variable fraction of newly synthesized proteins that do not fold efficiently.

A number of abundant ER-resident proteins that participate in retention of non-native conformers have been identified as chaperones and folding-assisting proteins. Protein disulfide isomerase (PDI), one of the first facilitators of protein folding described, is an abundant ER chaperone. PDI and other members of the thioredoxin family participate in disulfide bond formation as well as retention and degradation of targets of the quality control system. Of particular interest is one member of this family (ERp57) which, as will be described below, specifically associates with two ER-resident lectins, calnexin, (CNX), and calreticulin (CRT), and contributes to proper glycoprotein

folding. Another abundant ER protein, BiP (for 'binding protein'), that was originally identified as an ER retention factor for immunoglobulin heavy chains, participates in assisting protein folding through cycles of adenosine triphosphate (ATP) hydrolysis that regulate substrate binding and release.

N-Glycan Processing Reactions in the ER

Glycosylation of asparagine residues (N-glycosylation) in the mammalian cell ER presents two basic differences with respect to glycosylation of Ser/Thr units (O-glycosylation) in either the cytosol or the Golgi apparatus: (1) in the former case a glycan containing 14 monosaccharide units in most cells types is transferred *en bloc* to the polypeptide chain, whereas in O-glycosylation either a variable number of monosaccharide units are sequentially transferred (Golgi O-glycosylation) or a single of such units is added (cytosolic O-glycosylation) and (2) N-glycosylation occurs on not yet properly folded polypeptide moieties whereas in all cases O-glycosylation is a post-folding event. After being transferred to nascent chains in the ER, N-glycans are processed all along the secretory pathway. Whereas processing in the ER is basically similar in all eukaryotic cells for all N-glycans, Golgi processing reactions present a broad variation not only among different cell types but also different N-glycans belonging to the same or different glycoproteins may be differently processed within the same cell, thus yielding mature glycoproteins bearing glycan moieties with widely different structures. This diversity presents certain logic as the roles of protein-linked glycans in mature glycoproteins are mainly related to recognition phenomena. On the contrary, glycan processing in the ER is basically similar in all cells because, as it will be described below, the role of those reactions directly relates to a process common to all glycoproteins, namely the acquisition of their proper tertiary and quaternary structures.

Addition of N-glycans has several effects on protein folding, at least two of which may be observed not only *in vivo* but also in folding assays performed in test tubes with pure glycoproteins: (1) N-glycans provide bulky, highly hydrophilic groups that help to maintain glycoproteins in solution during the folding process and (2) the presence of glycans modulates protein conformations by forcing amino acids close to the linking Asn unit to be in the proximity of the water-glycoprotein interphase. This article does not deal with those effects but with *in vivo* folding facilitation and ER retention of improperly folded structures mediated by the interaction of a specific glycan structure (monoglucosylated glycans) with the ER lectins CNX and CRT.

The saccharide transferred in most wild-type cells from a lipid (dolichol) derivative to polypeptide chains as they enter the ER lumen has the composition $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ and the structure depicted in Figure 1. This is a well-conserved structure in nature as the same glycan is transferred in wild-type mammalian, plant, and fungal cells. There are some exceptions to this common pattern in certain protozoa, in which truncated N-glycans are transferred. The consensus glycosylation sequence (Asn-X-Ser/Thr, where X may be any amino acid except Pro) is not necessarily glycosylated. Apparently, N-glycosylation, that occurs when the involved Asn unit is about 10–12 amino acids far from the inner ER membrane surface, is hindered if the polypeptide chain rapidly adopts a secondary structure, in

Figure 1 Glycan structures. Lettering (a–n) follows the order of addition of monosaccharides in the synthesis of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ -P-P-dolichol. GI removes residue n and GII residues l and m. UGGT adds residue l to residue g. The $\text{Man}_8\text{GlcNAc}_2$ isomer formed by mammalian cell or *S. cerevisiae* ER α -mannosidase I lacks residues i, and l–n. The $\text{Man}_7\text{GlcNAc}_2$ isomer formed by the same enzyme lacks, additionally, residue k.

particular α -helices. Cell-free assays showed that the oligosaccharyltransferase transfers the triglucosylated glycan about 10–15-fold faster than $\text{Man}_9\text{GlcNAc}_2$. This property, as well as the strict distance between the receptor amino acid and the ER inner surface required for glycan transfer, determines a severe underglycosylation of glycoproteins synthesized by cell mutants unable to glucosylate the lipid-linked glycan. Folding is severely impaired in many, but not all, underglycosylated glycoproteins. The external Glc unit (residue n, Figure 1) is immediately removed from the protein-linked glycan by glucosidase I (GI), a membrane-bound α -(1,2)-glucosidase (see mammalian cell ER processing of N-glycans in Figure 2). Further deglycosylation mediated by glucosidase II (GII, an α -(1,3)-glucosidase) may remove the remaining Glc units (residues l and m, Figure 1). GII is a soluble heterodimer composed of catalytically active and inactive subunits. The latter, but not the former, contains an ER retrieval sequence at its C-terminus. One or two Man units (residues i and k, Figure 1) may be removed by ER α -mannosidase I.

An additional N-glycan-processing reaction occurring in the ER lumen is the transient glucosylation of glycoproteins: glucose-free glycans may be reglucosylated by the UDP-Glc:glycoprotein glucosyltransferase (UGGT) yielding $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$, $\text{Glc}_1\text{Man}_8\text{GlcNAc}_2$, and $\text{Glc}_1\text{Man}_7\text{GlcNAc}_2$ as reaction products. The structure of the first one is identical with that produced by partial deglycosylation of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ (Figure 1) and GII is also responsible for the *in vivo* deglycosylation of the monoglucosylated compounds formed by UGGT. This enzyme is present not only in mammalian but also in plant, fungal, and protozoan cells. Interestingly, UGGT is absent from *Saccharomyces cerevisiae* and in some protozoa such as *Tetrahymena thermophila*, *Toxoplasma gondii*, and *Cryptosporidium parvum*.

Figure 2 Glycan processing in the ER. G, M, GNA, D, and Pr stand for Glc, Man, GlcNAc, dolichol, and protein, respectively. OT, GI, GII, UGGT, and MI stand for oligosaccharyltransferase, glucosidase I, glucosidase II, UDP-Glc:glycoprotein glucosyltransferase and mannosidase I, respectively.

The Golgi apparatus of species belonging to the chordate phylum display an endomannosidase activity that degrades monoglycosylated *N*-glycans yielding Glc₁Man (plus Man₆₋₈ GlcNAc₂, depending on the substrate used). This enzyme has been described to occur also in the mammalian cell ER-Golgi intermediate compartment. It may be speculated that the role of this enzyme is to ensure a complete removal of Glc units, as their presence would hinder formation of complex-type glycans in the Golgi apparatus.

The UDP-Glc:Glycoprotein Glucosyltransferase

The transient addition of a terminal glucose residue to protein-linked glycans was discovered while studying *N*-glycan processing in trypanosomatid cells pulse-chased with [¹⁴C] Glc. These *in vivo* observations were then extended to other eukaryotes and it was soon established that transient reglucosylation of completely deglycosylated, protein-bound high mannose-type glycans was a general glycoprotein-processing reaction. Since glucose is not normally found on mature glycoproteins, transient reglucosylation was intriguing and the function of such apparent futile cycle of glucose addition and removal was not understood at the time. The reglucosylation of endogenous glycoproteins observed *in vivo* was reproduced in cell-free systems and the activity was localized by subcellular fractionation to the ER, where as mentioned above, deglycosylated glycoproteins that are subject to reglucosylation are formed by the action of GI and GII. As an *in vitro* assay for exogenous glycoprotein reglucosylation was developed, it was noticed that the substrate glycoprotein had to be denatured in order to be an acceptor in the reglucosylation reaction. This

observation raised the radical notion that glycoproteins had to be devoid of a native conformation to be recognized as substrates by UGGT. Based on this unique property, it was suggested that the enzyme (and monoglycosylated glycans) could be somehow involved in the so-called quality control of glycoprotein folding in the ER.

The involvement of protein recognition in glycosylation reactions was not without precedent. While most glycosyltransferases display specificity at the carbohydrate level (sugar acceptor, sugar donor, and linkage formed), some glycosyltransferases also recognize the protein to which the substrate glycan is bound to. The UDP-N-acetylglucosamine:lysosomal enzyme *N*-acetylglucosamine phosphotransferase selectively initiates formation of the Man 6-P epitope in lysosomal glycoproteins. In addition, the UDP-GalNAc:glycoprotein hormone *N*-acetylgalactosaminyltransferase selectively adds a GalNAc residue to secreted hormones. The substrates that reacted with UGGT *in vitro* did not appear to share any apparent common feature, except for their non-native conformation, as opposed to the other two glycosyltransferases, which maintain their rather narrow selectivity toward their respective glycoprotein substrates (lysosomal enzymes or glycoprotein hormones) when assayed *in vitro*. The requirement for non-native conformations implied that a wide range of substrates could be reglucosylated *in vivo*, since a large number of glycoproteins could potentially be recognized as substrates during their folding in the ER. Indeed, it is now accepted that many glycoproteins, independently from their final destination or of their soluble or membrane-bound status, behave as UGGT substrates during their folding process.

Purification of the enzyme from rat liver or *Schizosaccharomyces pombe* showed that activity resided in a single polypeptide of about 170 kDa, significantly larger than most glycosyltransferases. While most glycosyltransferases and glycosidases in the secretory pathway are type II membrane proteins, UGGT and its counteracting enzyme GII are soluble proteins. The purified UGGT has a neutral pH optimum, requires millimolar Ca²⁺ concentrations for activity, and uses UDP-Glc as substrate donor.

The ER membrane contains an integral protein responsible for the specific transport of UDP-Glc from its site of synthesis (the cytosol) into the lumen of the ER, where the sugar nucleotide serves as substrate for glycoprotein reglucosylation. Further, two GDPase/UDPas have been described in the mammalian cell ER lumen. Their role is probably to allow transport of UDP-Glc into the lumen by the known antiport mechanism by which entrance of sugar nucleotides into the ER or Golgi lumen is coupled to exit the corresponding nucleoside monophosphates.

The most significant finding in the isolation of UGGT was that the purified enzyme maintained its selectivity for denatured substrates. While it may still cooperate with other factors to recognize non-native conformations *in vivo*, the finding that pure UGGT exclusively reglucosylates non-native glycoproteins strongly suggests that the conformational sensing is performed primarily by the UGGT itself. No cofactors were found so far to modify the activity of isolated UGGT *in vitro*, and expression of UGGT cDNA is sufficient for glycoprotein reglucosylation in cells devoid of such activity (*S. cerevisiae*). It is now accepted that UGGT recognizes hydrophobic amino acid patches exposed in molten globule-like folding intermediates.

The Quality Control Mechanism of Glycoprotein Folding

Information mentioned above supports the mechanism depicted in **Figure 3** for the quality control mechanism of glycoprotein folding occurring in the ER. Accordingly, monoglucosylated glycoproteins generated either by partial deglucosylation of the transferred glycan or by UGGT-mediated glucosylation interact with CNX/CRT, two ER resident lectins that specifically recognize that structure. This interaction is followed by a shuttle between glucosylated (CNX/CRT-bound) and deglucosylated (CNX/CRT-free) forms catalyzed by the opposing activities of UGGT and GII. After acquiring their

proper tertiary structure, glycoproteins are deglucosylated by GII but not reglucosylated by UGGT and no longer bind to CNX/CRT. Permanently misfolded molecules continue to interact with the lectins, which are not sensing the conformation of their glycoprotein ligands. This task, all over the quality control process, is reserved to the reglucosylating enzyme, and cycles of binding and release to the lectins are mediated by independently acting enzymes (UGGT and GII) that covalently modify glycans. The CNX/CRT–glycoprotein interaction not only prevents secretion of folding intermediates and irreparably misfolded molecules, but also enhances folding efficiency as it prevents protein aggregation, premature oligomerization

Figure 3 Model proposed for the quality control of glycoprotein folding. Proteins entering the ER are N-glycosylated by the oligosaccharyltransferase (OST) as they emerge from the translocon (Sec61). Two glucoses are removed by the sequential action of GI and GII to generate monoglucosylated species that are recognized by CNX and/or CRT (only CNX is shown) that are associated with ERp57. The complex formed by the lectins and folding intermediates/misfolded glycoproteins dissociates upon removal of the last glucose by GII and is reformed by UGGT activity. Once glycoproteins have acquired their native conformations, either free or complexed with the lectins, GII hydrolyzes the remaining glucose residue and releases the glycoproteins from the lectin anchors. These species are not recognized by UGGT and are transported to the Golgi. Glycoproteins unable to properly fold are retro-translocated to the cytosol where they are degraded by the proteasome. One or more mannose residues may be removed by the ER α-mannosidase I (α-Man) during the whole folding process.

and promotes formation of the correct disulfide bonds by the CNX/CRT-ERp57 complex mentioned above. It is worth mentioning that UGGT and BiP recognize different folding conformers. The latter specifically binds heptapeptides with bulky hydrophobic amino acids in alternating positions exposed in early, extended conformations. On the contrary, UGGT glucosylates collapsed, molten globule-like conformers. As predicted by the different recognition pattern, sequential BiP–CNX/CRT interaction has been described for the *in vivo* folding of several glycoproteins. Folding facilitation mediated by CNX/CRT–glycoprotein interaction is not essential for the eukaryotic cell viability. Hindering monoglucosylated *N*-glycan formation either by disrupting *GI*-, *GII*-, or UGGT-encoding genes or by adding cell permeable inhibitors of the first two enzymes leads to the upregulation of other chaperones and folding assisting proteins that compensate the absence of lectin–glycoprotein interaction (unfolded protein response). Finally, it should be mentioned that irreparably misfolded glycoproteins are retained in the ER and eventually transported through a complex and not-yet fully understood process to the cytosol to be degraded in the proteasomes.

Glossary

α -Dystroglycan An essential component of the link between the cytoskeleton and the extracellular matrix in sarcolemma.

Fringe A β 1,3-*N*-acetylglucosaminyltransferase that modifies *O*-fucose residues on Notch. Alteration of the *O*-fucose structures results in modulation of Notch activity.

Notch A genetic locus originally identified in *Drosophila* that encodes a large cell surface receptor essential for many

stages of development. The Notch receptor is modified with both *O*-fucose and *O*-glucose.

O-linked carbohydrates Carbohydrate covalently linked to a protein through a hydroxyl group, usually of serine or threonine.

Rumi A protein *O*-glucosyltransferase that adds *O*-glucose to epidermal growth factor (EGF)-like repeats in the extracellular domain of Notch.

The addition of *O*-glucose appears to be essential for Notch activity.

Classes of O-Glycans

O-linked carbohydrate modifications are defined as any carbohydrate covalently linked to protein through a hydroxyl group, most commonly the hydroxyl of a serine or threonine residue. The classes of O-linked carbohydrate modifications are defined by the sugar directly linked to the hydroxyl group. In mammalian systems, at least six classes of O-glycans exist: *O*-GalNAc (*N*-acetylgalactosamine), *O*-GlcNAc (*N*-acetylglucosamine), *O*-xylose, *O*-fucose, *O*-glucose, and *O*-mannose. With the exception of *O*-GlcNAc, all of these modifications are found on proteins in extracellular spaces. *O*-GlcNAc is uniquely found on nuclear and cytoplasmic proteins. The *O*-GalNAc and *O*-xylose modifications constitute the largest and most structurally heterogeneous classes of O-linked modifications. The *O*-GalNAc modifications are usually referred to as mucin-type O-glycosylation because they are prevalent on mucins, and the *O*-xylose modifications are the glycosaminoglycans, the carbohydrate portion of proteoglycans. Two other O-linked modifications found on the hydroxyls of amino acids other than serine or threonine also exist in mammals: *O*-galactose on hydroxylysine of collagen and *O*-glucose on tyrosine of hyalogenin.

between the second and third conserved cysteine of the EGF-like repeat at the sequence $C^2XXXX(S/T)C^3$, where X can be any amino acid and S/T is the modified amino acid. Database searches show that over 100 proteins in mouse or human genomes contain this consensus sequence with an EGF-like repeat including all Notch receptors.

The *O*-fucose is added to EGF-like repeats by protein *O*-fucosyltransferase I (Pofut1, [Figure 2\(a\)](#)). It will only transfer fucose to serine or threonine in a consensus sequence within a properly folded EGF-like repeat, suggesting that the three-dimensional structure of the EGF-like repeat is necessary for recognition of the site. The gene for Pofut1 is highly conserved in metazoans, and mutations in the gene result in embryonic lethality in mice and fruit flies. The *O*-fucose can be elongated with a β 1,3-GlcNAc by a β 1,3-*N*-acetylglucosaminyltransferase called Fringe ([Figure 2\(a\)](#)). The GlcNAc can be further elongated with a galactose and sialic acid to form a mature tetrasaccharide in mammals. Elongation of the *O*-fucose monosaccharide is dependent on both the protein being modified and the tissue-dependent expression of the Fringe proteins. Fringe will modify *O*-fucose on some EGF-like repeats but not others, suggesting it recognizes not just the *O*-fucose, but also the surrounding protein structure.

O-Fucose on Epidermal Growth Factor-Like Repeats

O-Fucose modifications were initially identified on a number of serum glycoproteins involved in blood clot formation or dissolution including urinary-type plasminogen activator (uPA), tissue-type plasminogen activator, and factors VII, IX, and XII. Analysis of the sites of fucosylation on these proteins revealed that the fucose was attached to a serine or threonine in a consensus sequence within a protein module known as an epidermal growth factor (EGF)-like repeat. EGF-like repeats are small protein modules of ~ 40 amino acids found in dozens of cell-surface and secreted proteins ([Figure 1](#)). They are defined by the presence of six conserved cysteine residues that form three disulfide bonds. The *O*-fucose modification occurs

O-Glucose on EGF Repeats

O-Glucose modifications were also initially described on EGF-like repeats of serum glycoproteins such as factors VII and IX. Analysis of the sites of glycosylation revealed that the *O*-glucose modifies serine residues between the first and second conserved cysteine of the EGF-like repeat at the sequence: C^1XSXPC^2 ([Figure 1](#)). Over 50 proteins in mouse or human genomes are predicted to bear *O*-glucose modifications based on databases using this sequence, including all Notch receptors. *O*-Glucose is added to EGF-like repeats by a protein *O*-glucosyltransferase (Poglut) called Rumi, and the *O*-glucose can be further elongated with xyloses ([Figure 2\(b\)](#)). Like Pofut1, the gene encoding Rumi is highly conserved in

Figure 1 *O*-Fucose and *O*-glucose modifications occur within epidermal growth factor (EGF)-like repeats. A schematic representation of an EGF-like repeat is shown. Each circle represents an amino acid. Cysteines are shown in yellow, the *O*-glucose modification site is shown in green, and the *O*-fucose modification site is shown in blue. Amino acids important for defining the glycosylation sites are indicated. Disulfide linkages are represented by lines.

metazoans, and mutations in Rumi result in developmental defects in both flies and mice.

O-Fucose on TSRs

O-Fucose modifications have also been identified in a separate sequence context, that of thrombospondin type 1 repeats (TSRs). TSRs are a protein module found in numerous cell surface and secreted proteins of ~60 amino acids (Figure 3). TSRs are identified by the presence of several conserved residues, including six conserved cysteines that form internal disulfide bonds. The *O*-fucose modification on TSRs was first identified on human thrombospondin 1, and based on comparison of sequences surrounding the site of glycosylation on several TSRs, a consensus sequence for modification has been proposed: C¹X₂₋₃(S/T)C²X₂G. Database searches suggest that over 50 proteins in mouse or human genomes contain *O*-fucosylated TSRs. Modification of TSRs with *O*-fucose in several of these proteins, such as thrombospondin 2, properdin, F-spondin, ADAMTS13, and ADAMTS-like 1, has been confirmed using mass spectrometry. The *O*-fucose is added to the TSR by protein *O*-fucosyltransferase 2 (Pofut2), a distinct gene product from Pofut1 with nonoverlapping specificity (Figure 2(c)). The *O*-fucose can be elongated with a β 1,3-glucose by the action of an *O*-fucose- β 1,3-glucosyltransferase.

O-Mannose

O-Mannose modifications of proteins were originally described in yeast, but more recently have been shown to occur on mammalian proteins as well. The first description of *O*-mannose glycans in mammals was on brain proteoglycans.

Figure 2 Structures of *O*-linked carbohydrate modifications. For each modification, the potential structures are shown. Each monosaccharide is represented by the symbols defined at the bottom. The enzyme responsible for addition of each sugar is indicated with an arrow. (a) *O*-Fucose on EGF-like repeats. (b) *O*-glucose on EGF-like repeats. (c) *O*-fucose on TSRs. (d) *O*-mannose on mucin-like domain of α -dystroglycan. Pofut1, protein *O*-fucosyltransferase-1; Poglut (Rumi), protein *O*-glucosyltransferase; POMT, protein *O*-mannosyltransferase; β 3GnT, β 1,3-*N*-acetylglucosaminyltransferase; β 4GalT, β 1,4-galactosyltransferase; SiaT, sialyltransferase; α 3XylT, α 1,3-xylosyltransferase; β 3GlcT, β 1,3-glucosyltransferase; β 2GnT, β 1,2-*N*-acetylglucosaminyltransferase.

More recently, *O*-mannose glycans were detected on a specific protein, α -dystroglycan. Numerous *O*-mannose chains are attached to α -dystroglycan in a mucin-like domain. This is a region of the protein rich in serine, threonine, and proline where many of the serines and threonines appear to be modified. The mannose is added to the mucin-like domain by a protein *O*-mannosyltransferase (POMT). Two closely related genes encoding protein *O*-mannosyltransferases, POMT1 and POMT2, are required for POMT activity. Mutations in either of these genes cause a loss of *O*-mannosylation in mammals. The *O*-mannose can be elongated with a β 1,2-GlcNAc by an *O*-mannose- β 1,2-GlcNAc transferase, and the GlcNAc can be further elongated to a mature tetrasaccharide by the addition of galactose and sialic acid (Figure 2(d)). Other elongated forms of *O*-mannose are known to exist.

Figure 3 *O*-Fucose modifications occur on thrombospondin type 1 repeats (TSRs). A schematic representation of a TSR is shown. Each circle represents an amino acid. Cysteines are shown in yellow and the *O*-fucose site is shown in blue. Amino acids important for defining the glycosylation sites are indicated. Disulfide linkages are represented by lines.

Functions of *O*-Glycans

Determining the function of protein glycosylation has remained a problem for many years, partly because so many different proteins bear carbohydrate modifications. Carbohydrate modifications differ in function, depending on the protein they modify. Nonetheless, recent work has revealed specific functions for some of the *O*-linked modifications. The fact that these modifications are found on a smaller subset of proteins than more common types of glycosylation (e.g., *N*-glycosylation, mucin-type *O*-glycosylation, and glycosaminoglycans) has made evaluation of their functions somewhat more straightforward. Still, the principles learned from studying these modifications should be applicable to our understanding of other forms of glycosylation.

The Effects of *O*-Fucose in uPA–uPA Receptor Signaling

A role for the *O*-fucose modification in modulation of signal transduction was first proposed for the activation of the uPA receptor. As mentioned above, the EGF-like repeat of uPA was one of the first proteins to be demonstrated to bear an *O*-fucose modification. The uPA receptor is a mitogenic receptor, and it becomes activated upon binding to the EGF-like repeat of uPA. Interestingly, removal of *O*-fucose from the EGF-like repeat abrogates uPA receptor activation, although it has little or no effect on binding. Thus, the *O*-fucose appears to be essential for activation of the uPA receptor, and alterations in the level of *O*-fucose on uPA could potentially serve as a mechanism for modulating this activation.

The Effects of *O*-Fucose and *O*-Glucose in Notch Signaling

The concept that *O*-fucose and *O*-glucose modifications can regulate signal transduction events is strengthened by work on the Notch receptor. Notch is a cell-surface signaling receptor that plays many essential roles in the development of metazoans. Defects in the Notch signaling pathway lead to a number of human diseases, including several types of cancer, cerebral autosomal dominant arteriopathy with subcortical infarcts and

leukoencephalopathy (CADASIL, an inherited disease that results in recurrent strokes and early death), and a group of developmental disorders termed Alagille syndrome. Recent work has also implicated Notch in the pathogenesis of multiple sclerosis. Notch becomes activated upon binding to its ligands (members of the Delta family or the Serrate/Jagged family of proteins). Interestingly, the ligands are also cell-surface, transmembrane proteins. Thus, Notch becomes activated when an adjacent cell expresses ligand. Ligand binding causes the activation of proteases, releasing the cytoplasmic domain of Notch into the cytoplasm. The cytoplasmic domain then moves into the nucleus, where it associates with other proteins to regulate the transcription of a number of genes.

The extracellular domain of the Notch receptor is composed largely of tandem EGF-like repeats (36 consecutive EGF-like repeats in mammalian Notch1), many of which are modified with *O*-fucose and/or *O*-glucose. Both the *O*-fucose and *O*-glucose modifications are essential for Notch function. Abrogation of Pofut1 activity in *Drosophila* (by RNA interference) or in mice (by gene knockout) results in Notch phenotypes (i.e., the same phenotype observed when mutations are made in the Notch gene itself). Similarly, mutations in the Rumi gene (encoding Poglut) cause temperature-sensitive Notch phenotypes in flies. These results imply that if Notch is not modified by either *O*-fucose or *O*-glucose, it does not function properly. Since most Notch phenotypes arise early in development, these defects result in embryonic lethality.

In addition to being essential for Notch function, the *O*-fucose modification on Notch serves a regulatory role. The *O*-fucose on the EGF-like repeats of Notch can exist in either the monosaccharide or the tetrasaccharide form, depending on whether Fringe is expressed in the same cell. Fringe is a known modifier of Notch function, potentiating the signal received from Delta-like ligands, but inhibiting the signal received from Serrate/Jagged-like ligands. Although the details of how this modulation occurs are not known, these results indicate that the activation of Notch can be regulated by altering the structure of the *O*-fucose glycans on Notch. These results provide one of the clearest examples known of how a signal transduction pathway can be regulated by alterations in the glycosylation of the receptor.

The Role of *O*-Mannose in α -Dystroglycan Function

The recent demonstration of *O*-mannose on α -dystroglycan has led to the discovery of an essential role for these glycans in the musculoskeletal system. α -Dystroglycan forms a portion of an essential link between the cytoskeleton and the extracellular matrix in the sarcolemma. Specifically, α -dystroglycan binds to β -dystroglycan, a transmembrane protein that in turn interacts with cytoskeletal components. In addition, α -dystroglycan binds to laminin, an extracellular matrix component. Interestingly, the interaction with laminin appears to be mediated through the *O*-mannose oligosaccharides on α -dystroglycan, and alteration in the *O*-mannose tetrasaccharide appears to disrupt this interaction. Defects in any of the components in the link between the cytoskeleton and laminin in the muscle are known to cause various muscular dystrophies. For instance, defects in the enzyme that adds a GlcNAc to the *O*-mannose on α -dystroglycan (β 2GnT in [Figure 2\(d\)](#)), preventing formation of the mature tetrasaccharide, result in a form of congenital muscular dystrophy: muscle–eye–brain disease. Similarly, mutations in either POMT1 or POMT2 reduce *O*-mannosylation of α -dystroglycan, resulting in another congenital muscular dystrophy: Walker–Warburg syndrome. These results demonstrate that the *O*-mannose saccharides of α -dystroglycan play an essential role in the function of the dystroglycan–laminin interaction.

Potential Roles for *O*-Fucosylation of TSRs

Peters plus syndrome is an autosomal recessive human genetic disorder caused by mutations in the β 3GlcT that adds glucose to *O*-fucose on TSRs ([Figure 2\(c\)](#)). The patients display a

number of developmental defects, including anterior eye chamber defects, short stature, developmental delay, and increased incidence of cleft lip/palate. Although it is not known which protein(s) are responsible for these defects, these findings clearly demonstrate that *O*-fucose glycans on TSRs play very important roles in biology. Similarly, elimination of the gene encoding Pofut2 ([Figure 2\(c\)](#)) in mice causes early embryonic lethality. Together, these observations suggest that *O*-fucosylation of one or more of the 50 or more proteins predicted to be modified by Pofut2 is essential for their proper function.

Glossary

Asparagine-linked glycan An oligosaccharide covalently attached to the nitrogen atom of an asparaginyl residue of a protein or peptide.

Dolichol A polyisoprenoid lipid composed of five-carbon isoprene units and terminating with a hydroxyl that can be modified with groups such as phosphate, sugar phosphate, or oligosaccharyl pyrophosphate. The business-end (α) isoprene unit is reduced, while

the remaining isoprene units in dolichol retain double bonds.

Glycosidase An enzyme that can release a monosaccharide or oligosaccharide by cleavage of a glycosidic linkage.

Glycosyltransferase An enzyme that transfers a sugar residue from a donor substrate to a saccharide, protein, or lipid acceptor.

Lectin A protein with a binding site that is specific for sugars.

Biosynthesis and Structures of N-Linked Oligosaccharides

Synthesis of a Dolichol Pyrophosphate-Linked Oligosaccharide

N-linked glycosylation begins not with a polypeptide substrate, but rather with the polyisoprenoid lipid dolichol phosphate (Dol-P; also referred to as dolichyl phosphate by many workers). Dolichols are the longest lipids in humans, most commonly consisting of 95 carbons (19 isoprenyl units). Originating from the terminal phosphate of Dol-P, a 14-sugar oligosaccharide unit with a pyrophosphate linkage is assembled in a stepwise manner (Figure 1). The initial seven sugar additions of this pathway utilize enzymes and substrates present on the cytoplasmic leaflet of the endoplasmic reticulum (ER) membrane. First, a residue of GlcNAc-1-P is transferred from UDP-GlcNAc to Dol-P with release of UMP. The enzyme catalyzing this reaction, GlcNAc-1-P-transferase, is selectively inhibited by tunicamycin (TN). The resulting GlcNAc-P-P-Dol is sequentially modified with an additional residue of GlcNAc from UDP-GlcNAc and five residues of mannose from GDP-mannose. The product, $\text{Man}_5\text{GlcNAc}_2\text{-P-P-Dol}$, then flips to the luminal leaflet of the ER membrane. The subsequent extension of this molecule to $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-Dol}$, the completed dolichol-linked oligosaccharide (Figure 1, violet), requires a second function of Dol-P. On the cytoplasmic leaflet, Dol-P is modified with single residues of either mannose (from GDP-mannose) or glucose (from UDP-glucose). The resulting mannose-P-Dol (MPD) and glucose-P-Dol (GPD) then flip to the luminal leaflet where they serve as enzymatic donors for the final seven sugar residues of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-Dol}$. The specific arrangement of sugars in $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-Dol}$, including linkages and anomeric conformations, is highly conserved among most eukaryotes and can be essential for the functions of the oligosaccharide. Exceptions include most protists and some fungi, which synthesize smaller versions of the Dol-P-P-linked glycan.

Genetic defects in the synthesis of dolichol-P-P-linked oligosaccharides are responsible for the type-I congenital disorders of glycosylation (CDG). To date, 14 distinct genetic disorders (CDG types Ia–In) have been reported, all but type Ia

since 1998. The type-I CDGs affect specific sugar transferases as well as enzymes and factors involved in the synthesis of their donor substrates (Figure 1). Given the diversity of functions of N-linked glycans, it is not surprising that type-I CDG patients suffer from abnormalities of many organ systems. In contrast, the type-II CDGs affect remodeling of the oligosaccharide once transfer to newly synthesized protein has occurred, and may be caused by defects in processing glycosidases, glycosyltransferases, and nucleotide-sugar transporters.

Transfer of the Preformed Oligosaccharide Unit to Newly Synthesized Protein

The lumenally oriented oligosaccharide unit of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-Dol}$ is transferred to newly synthesized polypeptides that are also within the lumen of the ER, with release of Dol-P-P (Figure 1). The reaction is catalyzed by the multi-subunit enzyme oligosaccharyltransferase (OT). OT transfers oligosaccharide to sterically accessible asparaginyl residues in the tripeptide context asparagine-X-serine or threonine, where X can be any residue except proline. Transfer generally occurs cotranslationally; that is, once the polypeptide has emerged inside the luminal space but before its synthesis by the ribosome is completed. However, a small portion of acceptor sites become N-glycosylated posttranslationally, after the polypeptide chain is completed. It is now thought that two separate forms of OT may handle these distinct tasks. The resulting molecule of Dol-P-P is believed to be recycled back to Dol-P and returned to the cytoplasmic face to participate in additional synthesis of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-P-P-Dol}$, MPD, and GPD.

Glycosidase Digestion in the ER Lumen

Within minutes after transfer to protein, glycosidic digestion of the N-linked $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ (Figure 2, structure A) unit begins by the action of a family of ER-resident glycosidases. In a sequential manner, the terminal glucose residue is removed by ER glucosidase I, the remaining two glucose residues are removed by ER glucosidase II, and a single mannose is removed by ER mannosidase I. The resulting $\text{Man}_8\text{GlcNAc}_2$

Figure 1 Biosynthesis of the lipid-linked oligosaccharide $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-PP-Dol}$ in the endoplasmic reticulum. A molecule of Dol-P (upper left-hand corner) is converted into a dolichol pyrophosphate-linked 7-sugar saccharide ($\text{Man}_5\text{GlcNAc}_2\text{-PP-Dol}$) at the cytoplasmic face of the ER membrane. It is then extended in the lumen to the 14-sugar $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2\text{-PP-Dol}$ (violet; the detailed structure of the glycan is identical to that shown in **Figure 2**, structure A). The glycan unit is transferred to polypeptides synthesized by membrane-associated ribosomes (orange) as the polypeptides (green) emerge from the translocation pore (yellow). The resulting Dol-PP is converted to Dol-P and recycled to replenish the cytoplasmically oriented pool of Dol-P (red) used for the synthesis of GlcNAc-PP-Dol , Man-P-Dol , and Glc-P-Dol . The latter two molecules are synthesized cytoplasmically and translocated to the luminal face. Dol-P resulting from their consumption is not shown. Blue arrows indicate steps believed to be defective in type I congenital disorders of glycosylation. Bold red or blue arrows represent flipping reactions. The site of action of tunicamycin (TN) is also shown.

oligosaccharide is depicted in **Figure 2** (structure B). As discussed below, the intermediates $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$, $\text{Man}_9\text{GlcNAc}_2$, and $\text{Man}_8\text{GlcNAc}_2$ are particularly significant for folding and processing of glycoproteins. Cell-permeant inhibitors are available that block both of the ER glucosidases (castanospermine (CSN) and deoxynojirimycin (DN)), or ER mannosidase I (kifunensine (KF) and deoxymannojirimycin (DMN)). All of the N-linked oligosaccharide intermediates normally found within the ER are termed high mannose type to reflect the high proportion of mannosyl residues. Glycoproteins exported to the Golgi apparatus typically have glycans with eight mannosyl residues and no glucosyl residues, but in the event that a glycoprotein is exported before glucosidase digestion is completed, a Golgi endomannosidase exists that can remove any attached glucosyl residues plus the underlying mannosyl residue as a single unit (**Figure 3**).

Remodeling by Golgi Apparatus Glycosidases and Glycosyltransferases

The steps reviewed to this point are similar for most eukaryotes. However, within the Golgi apparatus N-linked oligosaccharides are remodeled with extensive variations in structure. These variations occur between different species, different organ systems of an individual species, different cell types of an organ system, different glycoproteins of a particular cell, and even among

different subpopulations (glycoforms) of a given glycoprotein. Many features of remodeling of N-glycans by the Golgi apparatus are covered elsewhere in this encyclopedia.

The remainder of this article is limited to remodeling in mammalian cells. It is useful to recall that the mammalian Golgi apparatus can be divided structurally and functionally into three components, known as the *cis*-, *medial*-, and *trans*-Golgi compartments, and is associated with the *trans*-Golgi network (TGN). The key enzymes involved in glycan remodeling are usually found in specific Golgi compartments or the TGN, and their physical locations in these secretory pathway organelles reflect both their order of action on secreted glycoproteins and their distinct substrate specificities (**Figure 2**). Enzymes involved in specialized remodeling (**Figures 3** and **4**) are also optimally located for accessing the correct oligosaccharide intermediate.

An elegant example of the orchestration of enzyme location and specificity comes from reactions that occur in the *cis*- and *medial*-Golgi compartments (**Figure 2**). Recall that $\text{Man}_8\text{GlcNAc}_2$ is the typical oligosaccharide intermediate on glycoproteins leaving the ER (structure B). Golgi mannosidase I, a resident of the *cis*-Golgi compartment, digests this oligosaccharide to form $\text{Man}_5\text{GlcNAc}_2$ (structure C; a different isomer than $\text{Man}_5\text{GlcNAc}_2$ formed as a dolichol-P-P-linked intermediate). Upon arrival at the *medial*-Golgi compartment, the $\text{Man}_5\text{GlcNAc}_2$ is modified by the first in a series of Golgi-associated

Figure 2 Remodeling of mammalian N-linked glycans in the endoplasmic reticulum, Golgi apparatus, and *trans*-Golgi network. Sugars in black form the invariant core that is retained after remodeling of N-linked glycans is completed; those in blue are removed by processing glycosidases; and those in red are added by Golgi-associated glycosyltransferases. The anomeric conformation of each glycosidic linkage is denoted α or β , with the linking group of the donor sugar preceding the comma and the linking group of the acceptor following the comma (GlcNAc, *N*-acetyl-D-glucosamine; Gal, D-galactose; Sia, sialic acid; Fuc, L-fucose). Processing of structure A ($\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$) begins by digestion with ER glucosidases I and II. Structures B through F are each formed by specific enzymes: B, ER mannosidase I; C, Golgi mannosidase I; D, GlcNAc transferase I; E, Golgi mannosidase II; F, GlcNAc transferase II. Structures A and B are associated with the ER; structure C is associated with the *cis*-Golgi apparatus; structures D–F are associated with the *medial*-Golgi apparatus; and structures G and H are associated with the *trans*-Golgi apparatus and the *trans*-Golgi network. Note that structure D can be converted to a hybrid-type glycan or, via structure E, a complex-type glycan such as those shown here (G and H). Sialic acid is commonly found in both $\alpha 2,3$ and $\alpha 2,6$ linkages on complex-type structures. The sites of cleavage by N-glycanase and endoglycosidase H (endo H) are indicated on structure A. Structure E and its products are resistant to endo H. Sites of action of the inhibitors castanospermine (CSN), deoxynojirimycin (DN), kifunensine (KF), deoxymannojirimycin (DMN), and swainsonine (SW) are shown.

glycosyltransferases, GlcNAc transferase I. Like all Golgi-associated glycosyltransferases, this enzyme uses a nucleotide-sugar donor. GlcNAc transferase I transfers a residue of *N*-acetylglucosamine (GlcNAc) from UDP-GlcNAc, forming a $\beta 1,2$ linkage with a specific mannosyl residue to yield $\text{GlcNAc}_1\text{Man}_5\text{GlcNAc}_2$ (structure D). GlcNAc transferase I is unable to recognize $\text{Man}_8\text{GlcNAc}_2$, and therefore the prior action of Golgi mannosidase I is essential. After addition of the GlcNAc residue, in most cases the $\text{GlcNAc}_1\text{Man}_5\text{GlcNAc}_2$ oligosaccharide is digested by another *medial*-Golgi enzyme, Golgi mannosidase II (which is inhibited by swainsonine (SW)), to generate $\text{GlcNAc}_1\text{Man}_3\text{GlcNAc}_2$ (structure E). Golgi mannosidase II is unable to recognize $\text{Man}_5\text{GlcNAc}_2$, and therefore requires the prior action of GlcNAc transferase I. Thus, it is clear that the subcellular locations of these enzymes must reflect their substrate specificities. Consequently, each enzyme is membrane associated and contains appropriate sorting/retention signals.

It is important to note that not all N-linked glycans are digested by Golgi mannosidases, and thus pass through the secretory pathway without further processing. This can be due to steric inaccessibility of the oligosaccharide or, as discussed later in the article, specialized competing reactions that supercede the typical processing reactions.

Digestion of $\text{GlcNAc}_1\text{Man}_5\text{GlcNAc}_2$ by Golgi mannosidase II uncovers a key mannosyl residue (structure E), allowing it to be modified by the addition of a residue of GlcNAc by GlcNAc transferase II (Figure 2). The resulting $\text{GlcNAc}_2\text{Man}_3\text{GlcNAc}_2$ oligosaccharide (structure F) has two exposed GlcNAc residues, and extension of these by additional transferases associated with the Golgi complex results in complex-type N-linked glycans such as structures G and H. As indicated earlier, the exact structures of complex-type glycans depend heavily on the organism, tissue, cell type, and protein, and are governed by which glycosyltransferases are expressed. These transferases

Figure 3 The roles of calnexin, calreticulin, unfolded glycoprotein glucosyltransferase, and endomannosidase in the formation and function of glycosylated N-linked oligosaccharides. A newly synthesized glycoprotein with a $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ glycan is shown in its unfolded state (orange). Removal of two glucose units forms a monoglucosylated glycan which can interact with the lectin sites of the chaperones calnexin and calreticulin. Subsequent dissociation from the lectin site allows the third glucose residue to be removed by glucosidase II. At this point, if the glycoprotein is properly folded (blue) an additional mannose unit will be removed and the glycoprotein will be exported to the Golgi apparatus. However, if the glycoprotein remains misfolded, its $\text{Man}_9\text{GlcNAc}_2$ glycan can be recognized by the unfolded glycoprotein glucosyltransferase to regenerate the monoglucosylated glycan and allow additional interaction with calnexin or calreticulin. The cycle of glucose removal and re-addition can be repeated many times for glycoproteins that are unable to fold. Eventually, on such misfolded glycoproteins one or more mannosyl units are removed from the $\text{Man}_9\text{GlcNAc}_2$ glycan to trigger destruction of the glycoprotein by a process termed ER-associated degradation (ERAD). If a glycoprotein folds properly, but exits the ER before glucose removal is completed, a Golgi-associated endomannosidase exists presumably to remove a disaccharide containing the remaining glucose unit and its underlying mannose unit (dashed arrows). Two distinct $\text{Man}_8\text{GlcNAc}_2$ isomers are formed by ER mannosidase I and Golgi endomannosidase, but each can be remodeled by Golgi-associated enzymes to form complex-type structures.

differ with regard to the sugar residue transferred (galactose, GlcNAc, fucose, GalNAc, and sialic acid), the anomeric conformation of the new linkage (α or β), the acceptor saccharide, and the hydroxyl on the acceptor that participates in the formation of the glycosidic linkage. As expected from the topological locations of the glycoprotein substrates, these transferases have catalytic sites facing the luminal spaces of Golgi compartments. The donor requirements of these transferases are met by specific transporters that import nucleotide sugars from the cytoplasm. These transporters also export the nucleotide mono- or di-phosphate by-products back to the cytoplasm. For a small fraction of oligosaccharides that fail to be digested by Golgi mannosidase II, the single exposed GlcNAc is available for extension to form hybrid-type N-linked glycans. These are so-named because they retain elements of both high-mannose-type and complex-type oligosaccharides.

A key variable among complex-type oligosaccharides is the number of branches, or antennae, that are formed. Each branch is initiated by a residue of GlcNAc attached to one of mannosyl residues in the $\text{Man}_3\text{GlcNAc}_2$ core. Complex-type structures with two to five branches have been reported, termed bi-antennary (Figure 2, structure G), tri-antennary, tetra-antennary (structure H), and penta-antennary. In most cases, sialic acid is the final sugar attached to N-linked glycans, introducing negative charges onto each branch of the complex-type oligosaccharide. However, negative charges can also result

from sulfation. It is with these final modifications that the glycoprotein is secreted or retained at the cell surface. The extent of branching appears to help regulate the functions of some surface membrane-bound glycoproteins. With more branches, cell-surface glycoproteins are better able to become engaged in lattices with lectins which also have access to the cell surface. The interactions within such lectin lattices retain glycoprotein components at the cell surface by hindering internalization. Thus, more branching may increase the surface residence time of a glycoprotein, and thereby regulate its ability to interact with hormones and other extracellular factors.

Methods for Analysis of N-Linked Glycoprotein Structure and Function

Binding to Plant Lectins

Plant lectins with a diverse range of specificities for the exposed monosaccharide, anomeric linkage, and other features of the oligosaccharide unit are commercially available. These can be used in many different ways: for example, as immobilized adsorbents attached to column matrices, as histochemical reagents when tagged with a reporter such as horseradish peroxidase, or to isolate subpopulations of cells when conjugated with fluorescent probes for flow sorting. Perhaps the best-known plant lectin is concanavalin A, which is selective for

Figure 4 Formation of the mannose-6-phosphate sorting signal for lysosomal enzymes. Glycoproteins enter the *cis*-Golgi compartment with $\text{Man}_8\text{GlcNAc}_2$ glycans (Figure 2, structure B). The majority of glycoproteins (blue) are processed normally and enter the secretory pathway by default. However, a specific UDP-GlcNAc:lysosomal enzyme GlcNAc-1-P transferase recognizes protein determinants that are common to lysosomal enzymes (green), and modifies the 6-hydroxyls of mannosyl residues of the $\text{Man}_8\text{GlcNAc}_2$ glycan with GlcNAc-1-P. An uncovering enzyme then removes the GlcNAc unit, leaving a mannosyl unit with a 6-phosphate modification. In the *trans*-Golgi network (TGN), enzymes with mannose-6-P units are then bound by mannose-6-P receptors (R), which escort the enzymes to endosomes. The acidic pH of the endosome allows the enzyme-receptor complex to dissociate. The receptors recycle to the TGN, and normal endocytic flow transports the released enzymes to lysosomes where the phosphate modification is removed. Thus, mature lysosomal enzymes have no trace of the mannose-6-P sorting signal. In certain disorders, addition of the GlcNAc-1-P unit is defective, resulting in the generation of a complex-type glycan and secretion of enzymes rather than delivery to lysosomes.

oligosaccharides with exposed α -mannosyl or α -glucosyl residues. Concanavalin A binds tightly to high-mannose-type and hybrid-type oligosaccharides, and weakly to bi-antennary complex-type oligosaccharides, but not to complex-type oligosaccharides with three or more branches.

Radiolabeling of Oligosaccharides

Incorporation of an isotopic label is a simple and highly sensitive way to permit study of the oligosaccharides themselves. In principle, to label the oligosaccharide unit in intact cells a radiolabeled metabolic precursor of any of the sugar residues can be used, but in practice the choice of precursor is limited by the specific radioactivity, intracellular pool dilution, and competing metabolic fates of precursors. $[2\text{-}^3\text{H}]\text{mannose}$ is frequently used because it can label all classes of N-linked oligosaccharides with high specific activity, and labeling is selective for glycoconjugates because diversion of the mannose to glycolysis by phosphomannose isomerase results in loss of the tritium from the sugar ring. *In vitro*, oligosaccharides are typically radiolabeled by incubation with an appropriate glycosyltransferase and a nucleotide sugar with an isotopically labeled sugar residue, or by selective oxidation of hydroxyls to aldehydes followed by reduction with $[^3\text{H}]\text{NaBH}_4$.

Digestion with Purified Endo- and Exo-Glycosidases

A useful selection of glycosidases that can be used to characterize N-linked glycans is now commercially available. Endoglycosidases cleave the bonds of unexposed sugar residues; two widely

used ones are endoglycosidase H and peptide:N-glycosidase F (also known as N-glycanase) as indicated by Figure 2. N-glycanase cleaves the asparaginyl-GlcNAc bond of almost all N-linked glycans, generating a free oligosaccharide with conversion of the asparaginyl residue to aspartic acid. Endoglycosidase H cleaves the β -linkage between the two GlcNAc residues. The asparaginyl-GlcNAc bond remains intact, and an oligosaccharide released by endoglycosidase H will have one fewer GlcNAc residue than the same oligosaccharide released by N-glycanase. Importantly, endoglycosidase H only cleaves high-mannose-type and hybrid-type oligosaccharides that have not been digested by Golgi mannosidase II (Figure 2).

Exoglycosidases cleave the linkages of exposed sugar residues. Specific glycosidases are available that can remove essentially every sugar found in N-glycans, and are often used sequentially as one glycosidase exposes the substrate of another. For example, the presence of sialic acid residues on an N-glycan can be determined with enzymes called sialidases or neuraminidases. As for other families of glycosidases, these can be obtained with broad or narrow specificities for the type of glycosidic linkage. After removal of sialic acid, the nature of the underlying sugar can be deduced with other exoglycosidases.

Inhibitors of Glycan Assembly and Processing

TN, a specific inhibitor of initiation of synthesis of dolichol-P-P-linked oligosaccharides, and CSN, DN, KF, DMN, and SW, inhibitors of N-glycan processing, can be valuable tools for determining the presence or class of an N-glycan, as well as for assessing N-glycan function. These inhibitors are effective

with intact cells and purified enzymes. Their sites of action are shown in **Figures 1** and **2**.

Introduction of Mutations in Genes Encoding Glycosidases and Glycosyltransferases

A very powerful approach for the assessment of N-glycan function and structure is the use of cell lines and rodent strains in which one or more glycosidases or glycosyltransferases have been inactivated by a spontaneous mutation, a chemically induced mutation, or a targeted gene disruption. The extensive collection of N-glycosylation mutations in Chinese hamster ovary cells has proved valuable in elucidating key steps in both the biosynthetic pathway discussed earlier in the article and the secretory pathway, in addition to testing the functions of specific intermediates and production of useful glycoproteins with defined N-glycans. Many of these cell lines were isolated by their resistance to toxicity of specific plant lectins. For example, cells of the *Lec1* complementation group lack GlcNAc transferase I activity. These have been used to establish the order of reactions discussed previously, to produce N-linked glycoproteins with Man₅GlcNAc₂ glycans instead of complex-type glycans, and to establish *in vitro* conditions for transfer of glycoprotein cargo between Golgi-derived vesicles.

Chemical and Physical Analysis of N-Glycans

The combined uses of glycosylation inhibitors, genetic mutations, and glycosidases can reveal a great deal of information about the number and types of N-linked glycans attached to a protein and their functions. Detailed structural information requires removal of the oligosaccharide unit from the polypeptide, followed by chemical and physical analysis. Conventional liquid chromatography, high-pressure liquid chromatography, and gel electrophoresis have been used extensively for both purification of oligosaccharides and determination of structural features. These are effective for separation of oligosaccharides by size, charge, or differences in column adsorption due to the particular arrangements of functional groups in the molecule. Several strategies are available to determine the monosaccharide compositions of purified oligosaccharides, including gas chromatography and liquid chromatography. The actual arrangements of the sugar residues, including linkage assignments, are achieved through a combination of glycosidase digestion, gas chromatography, mass spectrometry, and/or nuclear magnetic resonance spectroscopy.

N-Linked Oligosaccharides as Experimental Aids

Purification of N-Linked Glycoproteins

The presence of an N-linked glycan gives biological chemists a simple and effective way to enrich a glycoprotein of interest, by the use of lectin-affinity chromatography. A knowledge of the subcellular location of the glycoprotein allows the likely identity of the glycan class to be surmised, and an appropriate immobilized lectin to be chosen. A column prepared with such an immobilized lectin can then be used to isolate glycoproteins bearing the appropriate N-glycan from remaining

cellular components. These glycoproteins can then be gently eluted from the adsorbent by the addition of the correct competing saccharide. For example, chromatography with immobilized concanavalin A will strongly retain glycoproteins with high-mannose-type or hybrid-type glycans, which can be recovered by elution with a solution of α -methylmannoside. A similar approach can be used to prepare an enriched fraction of proteins that have traversed the Golgi apparatus, and therefore bear complex-type glycans, by chromatography with immobilized wheat germ agglutinin and elution with the competitor disaccharide chitobiose.

Radiolabeling and Tagging of N-Linked Glycoproteins

The methods described earlier for radiolabeling of N-glycans to facilitate glycan analysis are also useful for incorporating a radiolabel for other experimental purposes, without modification of the peptide backbone. A classic example is the sequential treatment of ceruloplasmin with neuraminidase and galactose oxidase, followed by reduction of the 6-aldehyde with [³H]NaBH₄ to generate an exposed tritium-labeled β -galactosyl residue. The resulting labeled asialo-ceruloplasmin is found to be rapidly cleared from the circulation by the liver. This result allows the identification of a novel β -galactoside selective asialoglycoprotein receptor in the liver. It has become an important model for receptor-mediated endocytosis studies.

Trafficking through the Secretory Pathway

As discussed earlier, N-linked glycan structures are modified as glycoproteins pass through the various compartments of the mammalian secretory pathway (**Figure 2**). This feature makes N-linked glycans extremely useful for monitoring the subcellular location of a glycoprotein of interest. The presence of a glycoprotein in almost any compartment along the secretory pathway can be determined by information gained from binding to plant lectins, reactivity with glycosidases, and/or labeling with sugar precursors. The most common use of these techniques takes advantage of the sensitivity of high-mannose-type glycans to endoglycosidase H, and the resistance to this enzyme that occurs after digestion with Golgi mannosidase II. Thus, the acquisition of endoglycosidase H sensitivity by a newly synthesized protein signifies that it is in fact a glycoprotein, and that a portion or all of its sequence is present in the ER luminal space. The subsequent loss of endoglycosidase H sensitivity reflects the arrival of the protein at the medial compartment of the Golgi apparatus (for most glycoproteins, 30–60 min after synthesis).

Functions of Selected N-Linked Glycans and Their Specific Cognate Lectins

Since the 1990s, there has been an explosion of discoveries of specific functions for protein-linked glycans, both asparagine-linked and serine/threonine-linked. Some functions of N-linked glycans are covered, in detail, elsewhere in this encyclopedia. A central concept revealed by these studies is that glycan function usually requires recognition by a specific cognate lectin. The ability to identify biologically significant glycan-lectin pairs

has been aided tremendously in recent years by the advent of glycan arrays, a powerful technology which involves large numbers of different chemically defined glycans immobilized into sectors on slides. These arrays are then queried with a fluorescently tagged lectin of interest, sometimes produced recombinantly from genetic material and with no other information other than that deduced from the predicted amino acid sequence. Glycan-lectin pairs are then identified with specialized fluorescence detection equipment which determines the sectors that have bound the lectin. By similar strategies, arrays of immobilized lectins can be queried with fluorescently labeled glycans to also identify glycan-lectin pairs.

In this section, two functions (albeit discovered prior to the advent of arrays) that highlight reactions covered in earlier sections are selected for discussion. These two examples illustrate how certain glycosyltransferases may recognize features of the polypeptide in addition to the glycan, and thus restrict modification to only special subclasses of glycoproteins. They also show how certain key modifications are transient, and are not found on the mature glycoproteins.

Monoglucosylated Oligosaccharides in ER Quality Control

As discussed earlier, removal of two glucosyl residues from the $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ N-linked oligosaccharide by the CSN-sensitive glucosidases I and II results in a monoglucosylated-processing intermediate, $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$. This intermediate is recognized by calnexin and calreticulin, resident ER chaperones with lectin activities specific for monoglucosylated oligosaccharides (Figure 3). Interactions with one of these lectin-chaperones can be crucial for folding and processing of nascent N-linked glycoproteins. Calnexin and calreticulin have essentially negligible recognition of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ (as well as oligosaccharides with zero or two glucose residues). Thus, treatment of cells with CSN blocks glycan-dependent interactions of chaperones with misfolded nascent N-linked glycoproteins because it prevents the formation of $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$ N-linked oligosaccharides. Calnexin and calreticulin bind to $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$ reversibly, and once dissociated from the lectin site of calnexin or calreticulin, the $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$ glycan can be digested to $\text{Man}_9\text{GlcNAc}_2$ by glucosidase II according to the scheme discussed earlier. After release of the glycan from the lectin site, calnexin and calreticulin appear to mediate further folding of their glycoprotein substrates due to lectin-independent chaperone activities.

In addition to processing of $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$, $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$ can be formed by reglucosylation of N-linked $\text{Man}_9\text{GlcNAc}_2$. This is achieved by a remarkable enzyme, the UDP-glucose:unfolded glycoprotein glucosyltransferase (Figure 3). The glucosyltransferase has two functional domains. A catalytic domain mediates the transfer of glucose from UDP-glucose to $\text{Man}_9\text{GlcNAc}_2$, forming the same $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$ structure as achieved by processing of $\text{Glc}_2\text{Man}_9\text{GlcNAc}_2$. A second recognition domain is able to identify physical features characteristic of misfolded proteins, presumably exposed hydrophobic surfaces. The binding of a $\text{Man}_9\text{GlcNAc}_2$ -bearing misfolded glycoprotein to the recognition domain allows reglucosylation by the catalytic domain. The regenerated $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$ glycan then gives the misfolded glycoprotein another opportunity to interact with calnexin/

calreticulin and be folded properly. The repeated actions of the lectin-chaperones calnexin and calreticulin, of glucosidase II, and of the ER glucosyltransferase account for the observation that certain glycoproteins with mutations that affect folding may retain the $\text{Glc}_1\text{Man}_9\text{GlcNAc}_2$ glycan for extended periods. Properly folded glycoproteins can be exported to the Golgi apparatus, while glycoproteins unable to achieve a properly folded conformation are destroyed by a process termed ER-associated degradation (ERAD) (Figure 3).

High-Mannose Oligosaccharides Bearing Mannose-6-Phosphate Residues as Sorting Signals for Lysosomal Hydrolases

The processing of $\text{Man}_8\text{GlcNAc}_2$ to $\text{Man}_5\text{GlcNAc}_2$ by the medial-Golgi enzyme mannosidase I was discussed earlier. However, hydrolases destined for the luminal space of the lysosome undergo a very different fate (Figure 4). On these proteins, the 6-hydroxyl groups of mannosyl residues are phosphorylated, producing high-mannose oligosaccharides containing mannose-6-phosphate. The mannose-6-phosphate then serves as a specific trafficking signal and allows the hydrolase to be deposited in the lysosome.

The mannose-6-phosphate recognition marker is created in two steps. First, GlcNAc-1-P is transferred to the 6-hydroxyl of a mannosyl residue of $\text{Man}_8\text{GlcNAc}_2$ by a specialized transferase, the UDP-GlcNAc:lysosomal enzyme GlcNAc-1-P transferase. Like the UDP-glucose:unfolded glycoprotein glucosyltransferase, this enzyme has two functional domains. The catalytic domain mediates transfer of GlcNAc-1-P to high-mannose-type glycans. The recognition domain binds to lysosomal hydrolases due to a special arrangement of amino acid side chains found only on these enzymes. Thus, the GlcNAc-1-P transferase is effective only with lysosomal hydrolases bearing high-mannose-type glycans. The GlcNAc-1-P transferase is found in the cis-Golgi compartment; thus, its reaction with $\text{Man}_8\text{GlcNAc}_2$ glycans can take place before digestion with Golgi mannosidase I. In the second step, the product is the substrate for another enzyme, known as the uncovering enzyme, which removes the GlcNAc residue and exposes the phosphate. Unlike the GlcNAc-1-P transferase, the uncovering enzyme has a catalytic domain but no known polypeptide recognition domain. The resulting mannose-6-phosphate-labeled hydrolase continues its movement along the secretory pathway, but undergoes no additional modifications of its glycan.

In the TGN, receptors for glycans with mannose-6-phosphate bind the hydrolases and escort them to endosomes. Usually, at least two mannose-6-phosphates must be generated per hydrolase for effective receptor binding. The acidic pH of the endosome causes release of the hydrolase from the receptor, which then recycles back to the TGN for additional rounds of sorting. The hydrolase is then deposited in the lysosome by normal vesicular traffic, and phosphatases remove the phosphate modification. Thus, mature lysosomal hydrolases bear high-mannose-type glycans without phosphate. Elucidation of this unique process has been aided by the discovery that it is disrupted in patients with I-cell disease and pseudo-Hurler polydystrophy. In these patients, heritable mutations cause loss of UDP-GlcNAc:lysosomal enzyme GlcNAc-1-P transferase activity. As a result, the mannose-6-phosphate sorting signal

is not formed and lysosomal enzymes are secreted instead of being deposited in lysosomes. This accounts for the storage of pathological waste products in the lysosomes of I-cell and pseudo-Hurler patients.

Glossary

Arabinogalactan protein (AGP) A heavily glycosylated cell-surface glycoprotein composed of large branched polysaccharide chains (containing predominantly arabinosyl and galactosyl residues) attached to hydroxyproline residues.

Extensin A moderately glycosylated cell-surface glycoprotein containing short linear arabinosyl chains attached to hydroxyproline residues and which may also contain single galactosyl residues attached to Ser residues.

Glycoprotein A compound containing carbohydrate (or glycan) covalently linked to protein (International Union of Pure and Applied Chemistry). The carbohydrate may be in the form of a monosaccharide, disaccharide(s), oligosaccharides, and polysaccharides.

Glycosylphosphatidylinositol (GPI) anchor A lipid modification added to the C terminus of selected proteins that anchors them in the outer layer of the lipid bilayer of the plasma membrane.

Types of Glycosylation

The classification of glycans as *N*-linked or *O*-linked reflects the type of covalent linkages between the amino acid residue in the core protein, and the first sugar of the glycan chain.

N-Linked Glycans

N-linked glycans are attached to core proteins through an amide nitrogen (N) on the side chain of selected asparagine (Asn) residues. They are attached to some, but not all, Asn residues in the motif Asn–Xaa–(Ser/Thr), where Xaa can be any amino acid except proline (Pro). Although the motif for the attachment of *N*-linked glycans is conserved in eukaryotes, the structure of the *N*-linked glycans differs in different organisms.

Attachment of an *N*-linked glycan is a multistep process. The first step is the addition of a 14-sugar preformed precursor oligosaccharide. This oligosaccharide contains *N*-acetylglucosamine (GlcNAc), mannose (Man), and glucose (Glc) and is the same in most eukaryotes (Figure 1(a)). The oligosaccharide is subsequently modified by glycosidases that remove selected sugars and by glycosyltransferases that selectively add sugars to specific positions.

The modifications can be temporally and spatially regulated, and are different in different organisms. An example of a complex-type *N*-linked glycan found in plants is shown in Figure 1(b). The Man₃GlcNAc₂ core (boxed) is found in all eukaryotic *N*-linked glycans; however, the terminal α -1,3-linked fucose and β -1,2 linked xylose residues attached to the Man₃GlcNAc₂ core are specific to plants. These plant-specific sugars on *N*-linked glycan are believed to contribute to the response experienced by people who are allergic to pollen and certain plant foods.

N-linked glycosylation is a common motif occurring on many plant proteins. *N*-linked glycans assist protein folding and are important for ensuring that only correctly folded proteins pass through the secretory system.

O-Linked Glycans

O-linked glycans are attached to the core protein through the oxygen (O) moiety of selected serine (Ser), threonine (Thr), and hydroxyproline (Hyp) residues. Hyp is a posttranslational modification of Pro that is commonly glycosylated in plants. Although Hyp is found in animal proteins (e.g., collagen), glycosylation of Hyp does not occur.

Glycosylation of Hyp exists in two different forms that depend on the arrangement of Hyp residues in the core protein. The first type of *O*-linked glycans attached to Hyp are short Ara chains (one to four) and are typically found on extensins (Figure 1(b)). In contrast, the arabinogalactan proteins (AGPs) contain large arabinogalactan (AG) polysaccharides attached to Hyp residues (Figure 1(c)). *O*-linked glycosylation of Thr is rare in plants, although it is common in animals. Glycosylation of Ser in plants is also relatively rare and usually consists of the addition of a single galactosyl residue.

In general, glycoproteins that contain *O*-linked glycans are destined for the cell surface and are found in the cell-wall/extracellular matrix (ECM), or in vesicles in transit to/from the cell surface. The addition of carbohydrate to proteins provides unique structural properties and informational complexity to the cell. The remainder of this article focuses on the *O*-linked glycosylation of Hyp residues.

Synthesis of *O*-Linked Glycans

Hydroxylation of Pro

For proteins to be glycosylated, they must enter the secretory system via the endoplasmic reticulum (ER) and subsequently the Golgi apparatus. Targeting is achieved by an N-terminal signal sequence of 20 amino acids in length and this signal is subsequently cleaved. In plants, the hydroxylation of Pro occurs in the ER as it does for animals.

Figure 1 (a) The first step in *N*-linked glycosylation is the addition of a 14-sugar preformed precursor oligosaccharide. This is subsequently modified by a series of glucanases and glycosyltransferases to produce a variety of *N*-linked glycans. An example of a complex-type *N*-linked glycan from plants is shown. The five core sugars (boxed) are conserved in plants, insects, and mammals. (b) An example of the *O*-linked glycosylation that occurs on extensins. Attached to the contiguous (uninterrupted) Hyp residues are one to four (1→2) α -L-Araf residues. (c) An example of the *O*-linked glycosylation found on AGPs. Attached to the predominantly noncontiguous Hyp residues are repeats of (1→3) β -linked Galp oligosaccharides with a degree of polymerization of about seven (large shaded region), separated by a periodate-sensitive linkage. The branching from the (1→3) β -linked Galp oligosaccharide backbone (as seen in the large shaded region) can occur from any Gal in the backbone. There may be as many as 10 repeats (only 5 are shown here). For simplicity, only a single Hyp residue has a polysaccharide chain attached. Reprinted from Gaspar YM, Johnson KL, McKenna JA, Bacic A, and Schultz CJ (2001) The complex structures of arabinogalactan-proteins and the journey towards a function. *Plant Molecular Biology* 4: 161–176.

Glycosyltransferases

O-linked glycosylation is poorly understood in plants. It is believed to occur sequentially with the addition of single sugars by a multitude of glycosyltransferases, starting in the ER and then further elaborated in the Golgi apparatus. The recent sequencing of several plant genomes has identified hundreds of plant glycosyltransferases. The lack of knowledge of these enzymes and the abundant heterogeneity of the *O*-linked glycans in plants means that it will be many years before we have a good understanding of the structure and synthesis of these glycans in plants.

Arrangement of Hyp Residues Dictates the Type of Glycans

Our understanding about the arrangement of glycans on the Hyp-rich glycoproteins is more advanced than our understanding of the individual glycan structures. In 1994,

Marcia Kieliszewski and Derek Larpport developed the Hyp contiguity hypothesis. This hypothesis suggests that contiguous (uninterrupted) Hyp residues are glycosylated with arabino-oligosaccharides (Figure 1(b)) and noncontiguous Hyp residues are glycosylated with AG polysaccharides (Figure 1(c)). Experimental support for this hypothesis continues to grow and recent work by Kieliszewski and colleagues shows that *O*-linked oligosaccharides and AG polysaccharides can be found in the same molecules, for example, LeAGP1 from tomato and gum arabic from *Acacia senegal*.

The Hyp contiguity hypothesis is useful for predicting *O*-linked glycosylation, although the precise rules governing the minimum length of clustered noncontiguous Hyp residues is not yet established. This is useful for modern biology where genes are generally characterized before the corresponding protein. Figure 2 shows the predicted arrangement of glycosylation of the major classes of Hyp-rich glycoproteins in *Arabidopsis thaliana*.

Figure 2 Schematic representation of the major classes of glycoproteins from *A. thaliana*. The models are based on AGP1 (At5g64310), AGP12 (At3g13520), AGP17 (At2g23130), FLA7 (At2g04780), EXT1 (At1g76930), and EXT6 (At2g24980), as downloaded from the Internet. For the AGPs and FLA7, all of the predicted Hyp glycosylation sites are shown. For the longer extensin protein backbones, the relative placement of the predicted arabinosaccharides and the AG polysaccharides is shown, but the number of glycan chains is not accurate. Not drawn to scale.

Hyp-Rich Glycoproteins Belong to Multigene Families

It is 10 years since the first extensin and AGP core protein genes were cloned from plants. The completion of the sequencing of the first plant genome, from *A. thaliana*, has provided a better understanding of the size and complexity of the Hyp-rich glycoprotein gene families. For example, the AGP gene family consists of 50 different genes in four distinct subclasses, and there are at least 20 different extensin genes. A major challenge for the future is determining the function of each family member.

Approaches for Determining the Function of Plant Glycoproteins

Structural Studies

The two best-studied classes of plant glycoproteins, the extensins and AGPs, have different structures and it is widely

accepted that they have different functions. Extensins are an integral part of the insoluble plant cell wall. The addition of arabinosaccharides to the extensin core proteins induces an extended polyproline-II helical structure giving extensins a rod-like property. The Ser-Hyp₃₋₄ regions of extensins are interspersed with amino acid residues (e.g., Tyr and Lys) that are important for cross-linking.

In contrast, AGPs are highly soluble components of the ECM. Rather than forming rods, they are believed to be almost spherical. In addition to polysaccharides, many AGPs also possess a lipid modification at their C terminus, in the form of a glycosylphosphatidylinositol (GPI) anchor. The finding that AGPs are GPI anchored helped explain their frequent association with the plasma membrane and provided additional clues to how they might be involved in signaling.

GPI anchors confer many different properties to animal proteins. These include (1) regulated release from cell surfaces, (2) inclusion in lipid rafts where they may be important components of signaling cascades, and (3) polarized targeting of proteins to specific cell surfaces. Although none of these features have been confirmed for AGPs, there is recent evidence suggesting that a GPI-anchored plant protein, COBRA, is polarized in specific cells of the root.

Immunohistochemistry

Much of the original interest in AGPs came from their abundance in female reproductive tissues. The two most commonly used tools for detecting AGPs are monoclonal antibodies that recognize carbohydrate epitopes, and the artificial carbohydrate antigen, β -glucosyl Yariv reagent (β -glcY). A variety of experiments using these tools suggest that AGPs are important for cell expansion and somatic embryogenesis. However, because these tools interact with carbohydrate epitopes present on multiple AGPs, they have limited use in determining the function of individual AGPs.

Genetic Approaches

Genetic approaches offer the best hope for finding the function(s) of individual plant glycoproteins. Identification of insertion (knockout) mutants in specific genes by sequencing the DNA flanking the site of DNA insertions is well advanced in *A. thaliana*. Current research efforts around the world aim to identify insertion mutants for every gene by 2010. By studying the phenotype of knockout mutants for genes involved in the synthesis and assembly of plant glycoproteins, it should be possible to determine the function of individual family members.

Future Studies

Once we know the function of individual glycoproteins, we can begin to answer the key question of whether the function of each glycoprotein resides in the protein core or in the microheterogeneity of the glycan epitopes, or in both. It is now widely recognized that carbohydrate epitopes on mammalian, *Drosophila*, and protozoan parasite glycoproteins are key determinants of biological specificity/function. The carbohydrate component of plant glycoproteins is expected to be equally important.

Glossary

Congenital disorders of glycosylation Inherited disorders of protein glycosylation involving the synthesis and transfer of the Dol-PP-oligosaccharide precursor sugar chain to protein or the subsequent processing of these *N*-linked oligosaccharides. The term can also apply to the addition of other types of sugar chains to proteins.

α -Dystroglycan An extracellular dystrophin–glycoprotein complex (DGC) component which is one of the major proteins known to contain O-mannose-based oligosaccharides. Mutations in genes that encode proteins needed for this type of glycosylation cause several types of muscular dystrophy.

DGC A large protein complex found in muscle, nerve, heart, and brain. It is composed of extracellular, transmembrane, and intracellular proteins. Mutations in different proteins of this complex cause different types of muscular dystrophy.

Glycosaminoglycan (GAG) A large complex sugar chain composed of alternating amino-sugar and uronic acid units.

Glycosylation The process of adding single (monosaccharides) or multiple sugars to proteins or lipids.

Glycosyltransferase An enzyme that transfers a sugar from an activated nucleotide donor to an acceptor protein, carbohydrate, or lipid.

Lipid linked oligosaccharide (LLO) Structure that is the precursor for *N*-linked glycans; it is composed of a sugar chain linked to dolichol through a pyrophosphate linkage.

Multiple hereditary exostosis (MHE) A dominant inherited disorder caused by mutations in two genes (EXT1 and EXT2) that encode a polymerase needed for the synthesis of heparan sulfate. Mutations cause painful recurrent outgrowths of bone and must be surgically removed.

Oligosaccharyl transferase complex A protein complex found in the endoplasmic reticulum where it recognizes the LLO sugar chain and attaches it to the newly synthesized proteins having the N-X-Thr/Ser consensus sequence for *N*-glycosylation.

Transferrin (Tf) An iron-carrying plasma glycoprotein that is especially susceptible to incomplete *N*-glycosylation caused by an insufficient amount of LLO or one that is inefficiently transferred to proteins.

All cells are covered with a dense forest of glycosylated molecules that consist of glycoproteins and glycolipids. These frostings often dictate and monitor the stability of newly synthesized proteins and glycolipids within the cell. On the surface, they help cells communicate with their neighbors to assess the state of the local neighborhood. Hundreds of enzymes are used in making the sugar chains and adding them to thousands of proteins. Inherited mutations in some of the biosynthetic enzymes cause human diseases that affect the function of many organs during embryonic development, childhood, and even as adults. This article covers these inherited protein glycosylation diseases and show where glycoobiologists studying sugar chain biosynthesis and function team up with physicians to define and understand the basis of these diseases.

Setting the Stage

About 1–2% of the human genome encodes proteins that synthesize or recognize sugar chains. Hundreds of different sugar chains decorate the surface of eukaryotic cells. The immense variety of sugar chains stems from variability in length (number of monosaccharides), kinds of linkage (alpha versus beta), spatial orientation (linkage) of the sugar, branching patterns (two or more sugars attached to another sugar),

and modifications by nonsugar elements (e.g., phosphate or sulfate). Adding each of these sugars or modification requires one or more separate enzymes. Sometimes coordinated groups of enzymes work in a specific order to add some sugars, or cleave others from the maturing chain. Cells express different complements of sugar biosynthetic enzymes (glycosyl transferases and glycosidases) and glycosylation of a single protein can vary in different cells. Moreover, the same sugar chain can have different functions depending on the protein it is linked to, and the cell expressing it. Loss of glycosylation capacity can have serious effects in some cells and much milder effects in others. This complexity means that the function of sugar chains has to be investigated case by case, protein by protein.

The linkage joining the sugar chain to the protein defines the type of glycosylation, as shown in [Table 1](#). Most of the glycosylation disorders have been identified in the *N*-linked oligosaccharide biosynthetic pathway since 1995. In 2002, incomplete glycosylation of α -dystroglycan with O-mannose-based sugar chains was found to be the cause of rare forms of muscular dystrophy. Defects in the biosynthesis of chondroitin and dermatan sulfate chains also cause diseases that affect growth of bone and connective tissues. Abnormalities in O-GalNAc modification can give rise to the autoimmune disease Tn syndrome and familial tumoral calcinosis. The failure to add phosphate or sulfate to sugar chains also causes glycosylation-based disorders.

Table 1 Major types of glycan–protein linkages

Glycan type	Linkage	Typical proteins	Location
N-linked	GlcNAc- β -Asn	Cell-surface receptors secreted proteins	All cells, blood, subcellular compartments (e.g., lysosomes)
O-linked	GalNAc- α -Ser/Thr	Secreted and cell-surface mucins	Cell-surface, gastrointestinal, and reproductive tracts
O-linked	Xyl- β -Ser	Chondroitin/dermatan sulfate	Extracellular matrix, cartilage
O-linked	Man- α -Ser/Thr	Heparan sulfate/heparin α -dystroglycan	Muscle, nerve cells

Figure 1 The types of congenital disorders of glycosylation (CDG). CDG types are based on finding mutations in genes whose products are involved in glycosylation. Type-I CDGs are defined by mutations in steps leading to the assembly and transfer of the lipid linked oligosaccharide chain (LLO) from the carrier lipid to potential N-glycosylation sites (N-X-T/S) on newly synthesized proteins in the ER. At the extreme left, the various monosaccharides (see symbol key) are first activated, and then they are incorporated one-by-one into a growing chain assembled on the carrier lipid, Dol-PP. The complete sugar chain is then transferred to the protein in a single step. Approximately, 40 genes are needed to carry out the first stage. Type-II CDG defects are defined as those that involve the sequential, highly ordered removal, and addition of individual sugars on protein-bound N-linked sugar chains. More than 20 additional genes are needed to synthesize a sugar chain typical of mammalian plasma glycoprotein, shown on the extreme right side. It is unclear exactly how many genes may truly be involved in this process, as the list continues to grow each year. To date, 11 separate type-II CDGs have been identified, and it is likely that many more will be found.

Congenital Disorders of Glycosylation

N-Glycosylation Overview

All N-linked chains are derived from a common dolichyl pyrophosphate (Dol-PP)-linked 14-sugar oligosaccharide (lipid-linked oligosaccharide (LLO)). It is composed of three glucose (Glc), nine mannose (Man), and two N-acetylglucosamine (GlcNAc) residues, forming a $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ chain that is transferred *en bloc* from the lipid carrier to proteins. Addition of each sugar unit occurs in a preferred order and requires at least 13 glycosyltransferases. The completed oligosaccharide chain is then transferred to the nascent polypeptide chain by the oligosaccharyl transferase (OST) complex located in the endoplasmic reticulum (ER) membrane. After the transfer, the sugar chain is processed. Specific glycosidases in the ER trim the $\text{Glc}_3\text{Man}_9\text{GlcNAc}_2$ chain, removing all Glc and some Man. As the proteins move to the Golgi, additional Man is often carved away and the chain is extended once again by addition

of two to four branches composed of GlcNAc, galactose (Gal), and sialic acid (Sia) to form complex-type sugar chains (Figure 1). Literally, hundreds of different sugar chain structures can be made by variations of this pathway.

Scope of the Disorders

Congenital disorders of glycosylation (CDG) result from genetic defects in the assembly, transfer, and processing of N-linked oligosaccharides. For convenience, the CDGs are divided into groups I and II. Originally, defective genes were lettered in chronological order of their discovery. More recently, a new nomenclature has been suggested to accommodate the rapidly rising number of new CDG genes (see, Table 2). The first group includes defects in the assembly of the LLO and its transfer to proteins, which probably requires at least 40 nonredundant genes. Defects in 18 of these genes have been shown to cause CDG. These include defects in the mobilization

Table 2 Inherited glycosylation disorders

<i>Disorders</i>		<i>Enzymatic or protein defect</i>	<i>Gene</i>	<i>OMIM^a</i>	<i>Frequent clinical features</i>
<i>CDG type</i>	<i>Formerly</i>				
PMM2-CDG	CDG-Ia	Phosphomannomutase Man-6-P→Man-1-P	<i>PMM2</i>	212065	Variable intellectual disability, hypotonia, seizures, coagulopathy, feeding problems, and liver fibrosis.
MPI-CDG	CDG-Ib	Phosphomannose isomerase Fru-6-P⇌Man-6-P	<i>MPI</i>	601785	Normal development, hypoglycemia, coagulopathy, diarrhea protein-losing enteropathy, vomiting, and liver fibrosis.
ALG6-CDG	CDG-Ic	Alpha-1,3-glucosyltransferase	<i>ALG6</i>	603147	Moderate intellectual disability, hypotonia, epilepsy, and esotropia
ALG3-CDG	CDG-Id	Alpha-1,3-mannosyltransferase	<i>ALG3</i>	601110	Severe psychomotor delay, optic atrophy, microcephaly, iris coloboma, and hypsarrhythmia
DPM1-CDG	CDG-Ie	Dolichol-P-Man synthase	<i>DPM1</i>	603503	Severe intellectual disability, hypotonia, epilepsy, mild dysmorphism, and coagulopathy
MPDU1-CDG	CDG-If	Dolichol-P sugar utilization protein	<i>MPDU1</i>	604041	Intellectual disability, short stature, ichthyosis, and pigmentary retinopathy
ALG12-CDG	CDG-Ig	Alpha-1,6-mannosyltransferase	<i>ALG12</i>	607143	Intellectual disability, hypotonia, facial dysmorphism, acquired microcephaly, and frequent infections
ALG8-CDG	CDG-Ih	Alpha-1,3-glucosyltransferase	<i>ALG8</i>	608104	Hepatomegaly, protein-losing enteropathy, renal failure, hypoalbuminaemia, oedema, and ascites
ALG2-CDG	CDG-Ii	Alpha-1,3-mannosyltransferase	<i>ALG2</i>	607906	Intellectual disability, hypomyelination, intractable seizures, iris colobomas, hepatomegaly, and coagulopathy
DPAGT1-CDG	CDG-Ij	GlcNAc-1-P transferase	<i>DPAGT1</i>	608093	Severe intellectual disability, hypotonia, seizures, microcephaly, and exotropia
ALG1-CDG	CDG-Ik	Beta-1,4-mannosyltransferase	<i>ALG1</i>	608540	Severe intellectual disability, hypotonia, intractable seizures, nephrotic syndrome, acquired microcephaly, fever, coagulopathy, and early death
ALG9-CDG	CDG-IL	1,2-mannosyltransferase	<i>ALG9</i>	608776	Hepatomegaly, hypotonia, seizures, and severe microcephaly
DOLK-CDG	CDG-Im	Dolichol kinase	<i>DOLK</i>	610768	Ichthyosis, baldness, hypotonia, dialyated cardiomyopathy, and hypoketotic hypoglycemia
RFT1-CDG	CDG-In	Man(5)GlcNAc flippase	<i>RFT1</i>	612015	Hepatomegaly, developmental delay, hypotonia, seizures, and sensorineural deafness
DPM3-CDG	CDG-Io	Dolichol-P-Man synthase	<i>DPM3</i>	612937	Normal development, dystroglycanopathies, and stroke like episode
TUSC3-CDG		Subunit of the OST complex	<i>TUSC3</i>	611093	Nonsyndromic intellectual disability
IAP-CDG		Subunit of the OST complex	<i>IAP</i>	–	X-linked nonsyndromic intellectual disability
ALG11-CDG	CDG-Ip	Alpha-1,2-mannosyltransferase	<i>ALG11</i>	–	Develop intellectual disability, muscular hypotonia, seizures, early death
MGAT2-CDG	CDG-IIa	N-acetylglucosaminyltransferase II	<i>MGAT2</i>	212066	Intellectual disability, dysmorphism, stereotypies, seizures
GCS1-CDG	CDG-IIb	α-1,2-glucosidase	<i>GCS1</i>	601336	Dysmorphism, hypotonia, seizures, hepatomegaly, hepatic fibrosis; death at 2.5 months
SLC35C1-CDG	CDG-IIc	GDP-fucose transporter	<i>FUCT1</i>	266265	Severe intellectual disability, hypotonia, elevated peripheral neutrophils.
B4GALT1-CDG	CDG-IId	Beta-1,4-galactosyltransferase	<i>B4GALT1</i>	607091	Hypotonia (myopathy), spontaneous hemorrhage, Dandy– Walker malformation
COG7-CDG	CDG-IIe	Conserved oligomeric Golgi subunit 7	<i>COG7</i>	608779	Early Fatality, dysmorphism, hypotonia, intractable seizures, hepatomegaly, progressive jaundice, recurrent infections, cardiac failure, excessive skin

(Continued)

Table 2 (Continued)

<i>Disorders</i>		<i>Enzymatic or protein defect</i>	<i>Gene</i>	<i>OMIM^a</i>	<i>Frequent clinical features</i>
<i>CDG type</i>	<i>Formerly</i>				
SLC35A1-CDG	CDG-II _f	CMP-sialic acid transporter	<i>SLC35A1</i>	605634	Thrombocytopaenia, no neurological symptoms; normal transferrin, abnormal platelet glycoproteins
COG1-CDG		Conserved oligomeric Golgi subunit 1	<i>COG1</i>	606973	Mild MR, hypotonia, growth retardation, progressive microcephaly, hepatosplenomegaly
COG8-CDG	CDG-II _h	Conserved oligomeric Golgi subunit 8	<i>COG8</i>	611182	MR, hypotonia, and encephalopathy
COG5-CDG		Conserved oligomeric Golgi subunit 5	<i>COG5</i>	—	Moderate intellectual disability, cerebellar atrophy, and hypotonia,
COG4-CDG		Conserved oligomeric Golgi subunit 4	<i>COG4</i>	—	Mild intellectual disability, mild dysmorphia, epilepsy, recurrent respiratory infections, and mild ataxia
ATP6V0A2-CDG		Golgi pH regulator	<i>ATP6V0A2</i>	219200	Cutis laxa, wrinkly skin, connective tissue weakness, large fontanelle, and —/+ variable intellectual disability
Achondrogenesis type 1A		Golgi structure	<i>GMAP-210</i>	200600	Infants have soft skull bones, short ribs that fracture easily, extremely short limbs, and lack normal ossification in the spine and pelvis
Congenital dyserythropoietic anemia (CDA II)	Hempas	ER–Golgi protein trafficking	<i>SEC23B</i>	224100	Anemia, jaundice, splenomegaly, and gall bladder disease
Cranio-lenticulo-sutural dysplasia (CLSD)		ER–Golgi protein trafficking	<i>SEC23A</i>	607812	Facial dysmorphisms, sutural cataracts late-closing fontanels, and skeletal defects
<i>Muscular dystrophy</i> Walker–Warburg syndrome		Putative O-mannosyltransferase	<i>POMT1</i>	268870	Severe muscle weakness, death in infancy, absent psychomotor development, neuronal migration disorder, and ocular abnormalities
Muscle–eye–brain disease (MEB)		O-mannosyl glycan synthesis	<i>POMGnT1</i>	253280	Severe muscle weakness, intellectual disability, epilepsy, neuronal migration disorder, and ocular abnormalities
Fukuyama-type congenital muscular dystrophy (FCMD)		Putative glycosyltransferase	<i>Fukutin</i>	253800	Severe proximal and axial weakness, intellectual disability, and epilepsy neuronal migration disorder
Congenital muscular dystrophy type 1C (MDC1C)		Fukutin-related protein, a putative glycosyltransferase	<i>FKRP</i>	606612	Hypotonia, impaired motor development with respiratory muscle weakness
Congenital muscular dystrophy type 1D (MDC1D)		Putative glycosyltransferase	<i>LARGE</i>	608840	Muscular dystrophy with profound intellectual disability
Hereditary inclusion body myopathy / distal myopathy with rimmed vacuoles		UDP-GlcNAc epimerase/kinase	<i>GNE</i>	600737	Adult onset myopathy that spares quadriceps
<i>Other types</i>					
1-cell disease		GlcNAc-1-P transferase	<i>GNPTA</i>	252500	Severe developmental abnormalities
Multiple hereditary exostoses		Heparan sulfate co-polymerase	<i>EXT1, EXT2</i>	133701	Bony outgrowths
Macular corneal dystrophy		GlcNAc-6-sulfotransferase	<i>CHST6</i>	605294	Progressive corneal opacity
Adducted thumb-clubfoot syndrome		N-acetylgalactosamine 4-O-sulfotransferase 1	<i>CHST14</i>	601776	Congenital contractures of thumbs and feet with joint instability, facial clefting, coagulopathy, distinct facial appearance, thin and translucent skin, heart, kidney, or intestinal defects

(Continued)

Table 2 (Continued)

<i>Disorders</i>	<i>Enzymatic or protein defect</i>	<i>Gene</i>	<i>OMIM^a</i>	<i>Frequent clinical features</i>
<i>CDG type</i>	<i>Formerly</i>			
Ehlers–Danlos syndrome progeroid form	Xylosylprotein β -1,4-galactosyltransferase	<i>B4GALT7</i>	130070 604327	Hypotonia, delayed development, connective tissue abnormalities, and loose skin
Diastrophic dysplasia achondrogenesis	Anion (sulfate) transporter	<i>DTDST</i>	606718 600972	Scoliosis, club foot, and premature calcification
Spondylo-epimetaphyseal dysplasia	3'-phosphoadenosine-5'-phosphosulphate synthase (PAPS)	<i>ATPSK2</i>	603005	Abnormal skeletal development and linear growth
Familial tumoral calcinosis	GalNAc transferase	<i>GALNT3</i>	211900	Massive calcium deposits in skin and tissue
Tn syndrome	Chaperone of β -1,3GalT	<i>COSMC</i>	230430	Anemia, leukopenia, and thrombocytopenia (somatic mutation)
Schneckenbecken dysplasia	UDP-GlcA / UDP-GalNAc Golgi Transporter	<i>SLC35D1</i>	610804	Severely shortened long bones with bowing of limb bones and unossified vertebral bodies
Peters Plus syndrome	B-1,3 Glucosyltransferase specific for O-Fucose on thrombospondin type 1 repeats	<i>B3GALT1</i>	261540	Intellectual disability with prenatal growth delay, short stature, brachymorphism, short limbs, and sometimes cleft palate
<i>Defects in glycolipid synthesis</i>				
Paroxysmal nocturnal haemoglobinuria	PI-GlcNAcT	<i>PIGA</i>	311770	Complement-mediated hemolysis (somatic mutation)
Amish infantile epilepsy	Sia2,3Gal β 1,4Glc-Cer synthase (GM3)	<i>SIAT9</i>	609056	Tonic-clonic seizures, arrested development, and neurological decline
Autosomal recessive GPI anchor deficiency	1st Mannosyltransferase in GPI biosynthesis	<i>PIGM</i>	610273	Venous thrombosis and seizures caused by SP1 promoter mutation

^aOMIM: Online Mendelian Inheritance in Man.

and interconversion of monosaccharide precursors or defective glycosyltransferases used to link these sugar units. The second group involves processing of the sugar chains. It is uncertain how many genes may be involved in the step because various genes encode enzymes that may catalyze the same or similar sugar-transfer reactions. In addition, genes from this group involve glycosidases, glycosyl transferases, and Golgi-associated donor nucleotide transporters that deliver substrates to the Golgi lumen and Golgi trafficking proteins. Thus far, defects in 14 genes from this group cause CDG. It is becoming clear that defects in Golgi maintenance and trafficking represent a growing number of CDG cases. Currently, there are ~1000 confirmed cases of all types of CDG worldwide, which probably represent a small percentage of the total patients. It is safe to say that the entire group of CDGs is severely under diagnosis, and that we are now only seeing the 'tip of the iceberg'.

Laboratory Diagnosis of CDG

CDG patients are often misdiagnosed early on because their symptoms resemble other generic disorders. CDG-Ia patients are sometimes mistaken for having inherited mitochondrial disorders or cerebral palsy. This is understandable since glyco-biology is not part of a typical medical education or training program and most practicing physicians have a limited exposure to glycobiology. Fortunately, most CDG patients can be

diagnosed by a simple blood test to analyze the glycosylation status of transferrin (Tf). Abnormal Tf is detected by isoelectric focusing, or by electrospray ionization-mass spectrometry. Many other proteins are misglycosylated, but Tf appears to be especially sensitive to limitations in the amount of LLO precursor. These biochemical analyses provide clues to the defect, but they cannot pinpoint the defective gene, since many defects produce the same altered pattern.

Biochemical Overview

All of the CDGs are autosomal recessive disorders and they result from an insufficient amount of precursor molecules or from deficient glycosyltransferases or sugar-processing glycosidases. For a complete listing, see Table 2. By far the most common type, CDG-Ia (OMIM 212066), is caused by mutations in the gene encoding phosphomannomutase (Man-6-P $\rightarrow$ Man-1-P). Mutations reduce the amount of GDP-Man, resulting in insufficient LLO. This leaves some of the normal glycosylation sites on many proteins unoccupied, which can lead to their misfolding and degradation. Sometimes the misfolded proteins accumulate in the ER, activating cell apoptosis. CDG-Ib (OMIM 602579) results from mutations in the *MPI* gene encoding phosphomannose isomerase (PMI) (fructose-6-P $\rightarrow$ Man-6-P), just one metabolic step away from phosphomannomutase. The clinical pictures of CDG-Ib and CDG-Ia

patients are quite different. CDG-Ic (OMIM 603147) is caused by mutations in *ALG6*, which encodes an α -1,3-glucosyltransferase used to add the first Glc to the immature LLO precursor. Chains lacking glucose are transferred to proteins less efficiently than full-sized ones. Finally, the OST complex mediates the transfer of the final mature glycan product to the protein. Mutations already identified in two of the OST subunits will provide insight into understanding how the glycan chains are transferred to proteins. But identification of these patients will be more challenging since they have normal Tf.

Group II CDGs are defined as those that affect the processing of the protein-bound sugar chains. Only a few patients have been identified with each of these disorders, and most, but not all of them can be diagnosed by analysis of Tf. Thus far, the most common group II CDG is composed of patients with defects in the conserved oligomeric Golgi (COG) complex. The COG complex is an octameric structure whose stability is dependent on the presence of functional subunits; mutations in various subunits destabilize complex. The stabilized complex is required for intracellular transport of the glycosylation machinery. To date, mutations have been identified in five of the eight subunits (see [Table 2](#)).

Several other genetic disorders have provided key insight into the roles of protein trafficking and its effects on glycosylation. For example, mutations in Golgi pH regulator ATP6V0A2 have shown the role in glycosylation and trafficking play in maintaining extracellular matrix integrity as mutations result in autosomal recessive cutis laxa type II. Mutations in SEC23A, a COPII component, results in cranio-lenticulo-sutural dysplasia, a rare disorder with defects in clearing secreted proteins resulting in a dysfunctional ER. Congenital dyserythropoietic anemia (CDA-II/HEMPAS) results in ineffective erythropoiesis due to mutations in the COPII component SEC23B, which appears to be involved in erythroid differentiation.

Many of these proteins have several homologs whose function is conserved within similar pathways; but it is becoming clearer that certain protein components are required for non-redundant functions.

Clinical Features of CDG

The most common clinical features in various types of CDG are shown in [Table 2](#). There is considerable clinical heterogeneity even within a specific type of CDG. Intellectual disability ranging from mild to severe and hypotonia are consistent features in all patients except type-Ib. Other neurological findings include ataxia (Ia and Ic), seizures, and stroke-like episodes. Cerebellar hypoplasia (Ia and Ic), delayed myelination (Ie, IIa, and IIb), microcephaly, and atrophy of the cerebrum (Ia, Ic, Id, and Ie) are seen. Sometimes the cognitive deficiency can be mild. Nearly all patients have feeding problems and fail to thrive. Strabismus, abnormal fat distribution, and retracted nipples are common, especially in the CDG-Ia group.

Mortality in CDG-Ia children is about 20% during the first few years, but they stabilize after childhood. Substantial survival means that many adult CDG patients remain undiagnosed.

CDG-Ib, caused by deficiency in MPI, is substantially different from all the others; in that case mental development and

the nervous system are normal. The reason for this is unknown. These patients have serious gastrointestinal problems, protein-losing enteropathy (loss of proteins through the intestine), low plasma albumin, coagulopathy (fast clotting), and hypoglycemia. A substantial number of patients died before they received a diagnosis, which is unfortunate, since this type of CDG can be treated effectively.

Less common clinical features can periodically help to define a CDG subtype include ichthyosis, ocular coloboma, cataracts, abnormal genitalia, and muscular dystrophy.

Therapy for CDG

The effective therapy for CDG-Ib is oral mannose. Mannose bypasses the fructose-6-P $\rightarrow$ Man-6-P block to replenish the depleted GDP-Man pools. A mannose transporter delivers mannose to the cells and hexokinase converts it into Man-6-P. Mannose therapy reverses the hypoglycemia and coagulopathy within a few weeks, and within 1–2 months plasma protein levels become normal and protein-losing enteropathy disappears. Some patients have been treated for over 12 years without side effects. Growth during childhood is metabolically demanding and mannose supplements are most important then. It is encouraging that none of the adult patients with proven CDG-Ib is currently taking mannose, suggesting that it will not be a lifelong requirement. It is important to point out that there is no evidence that healthy people require mannose supplements. Vendors of complex nutraceutical mannose fail to point out that the natural plant polysaccharides they sell are non-digestible in the human intestine to produce bio-available mannose. Fucose supplements have also been used to treat patients with CDG-IIc who have a defective GDP-Fucose transporter. Fucose enters the cell and apparently increases the GDP-Fucose pool driving it into the Golgi through the impaired transporter with some residual activity. Within a day, fucose treatment corrects the patients' elevated circulating neutrophil by generating a selectin ligand needed for neutrophil rolling on the endothelium prior to their transmigration into the tissues. Infections cease and health improves. Unfortunately, fucose does not improve or reverse the intellectual disability.

Congenital Muscular Dystrophies

α -Dystroglycan is a peripheral membrane component of the dystrophin–glycoprotein complex (DGC) found in muscle, nerve, heart, and brain. This protein binds to merosin in extracellular matrix bridging it to the cytoskeleton molecules that include dystrophin and actin. Mutations in dystrophin cause Duchenne and Becker muscular dystrophies, while assorted mutations in merosin and sarcoglycans cause other inherited muscular dystrophies. Total systemic loss of α -dystroglycan is embryonic lethal. In addition, this protein is the major carrier of O-mannose-based sugar chains. In α -dystroglycan, these sugar chains cluster together in a small mucin-like domain of where they mediate many of the critical stabilizing interactions with the other matrix molecules such as merosin, neurexin, and agrin, depending on which cells express α -dystroglycan. Several kinds of muscular dystrophies

including muscle–eye–brain (MEB) disease, Fukuyama-type congenital muscular dystrophy (FCMD), Walker–Warburg syndrome, and limb–girdle muscular dystrophy, involve mutations in the genes needed for the biosynthesis of these chains (Table 2). These mutations also appear to affect neuronal migration in the developing brain, thus accounting for the combined effects on muscle and brain development. Studying the glycosylation of α -dystroglycan will be important to understand how these pathologies develop. However, α -dystroglycan is not the only protein that carries these sugar chains. In fact, one out of four O-linked chains in the brain is O-mannose based.

One form of adult onset muscular dystrophy, hereditary inclusion body myopathy type II, is due to mutations in an enzyme involved in the biosynthesis of CMP-sialic acid, the universal activated donor for addition of sialic acid. The mutations appear to have only moderate (50–60%) reduction in the activity of the enzyme (UDP-GlcNAc epimerase-kinase) which is lethal when totally deleted. Preliminary studies in fibroblasts and muscle cells from the patients show that addition of sialic acid is reduced and that supplying sialic acid or N-acetylmannosamine (the product of the impaired enzyme) can correct the glycosylation. This suggests that patients might benefit from supplements of these sugars. In fact, mice carrying patient-like mutations in this enzyme respond well to diets supplemented with ManNAc, sialic acid, or even sialyllactose.

Defects in Proteoglycan Biosynthesis Cause Disease

Incomplete or impaired synthesis of glycosaminoglycan (GAG) chains also cause inherited disorders. The bony outgrowths found in patients with the dominant disorder, multiple hereditary exostoses (MHE) result from mutations in the copolymerase that assembles alternating units of glucuronic acid and GlcNAc in heparan sulfate. Ehlers–Danlos syndrome, which causes a form of progeria is caused by mutations a galactosyltransferase used for assembly of the tetrasaccharide core linkage common to heparin, heparan sulfate, chondroitin, and dermatan sulfate. Macular corneal dystrophy that leads to corneal opacity is caused by loss of a specific sulfotransferase that modifies a special type of keratan sulfate found in the cornea. Sulfate is such an important component for making extracellular matrices that cells have a cell-surface transporter that delivers sulfate to the cytoplasm. Mutations in the transporter cause multiple cartilage and bone malformations and in

the most severe forms prenatal lethality results from respiratory insufficiency.

Glycosylation Disorders: The Next Generation

The very complexity of sugar chain assembly practically guarantees that more glycosylation disorders will be discovered. Finding defects in the N-linked pathway has been relatively easy because many of the steps involve only a single enzyme, many of which have strict substrate requirements. In addition, Tf provides an unusually robust assay for defective N-glycosylation. Except for α -dystroglycan, the other pathways lack a similar diagnostic champion. New disorders that compromise glycosylation will probably be discovered in the synthesis of O-GalNAc-linked sugar chains, GAGs, and in the assembly, organization, or recycling of proteins in the Golgi apparatus. These causes may be more difficult to identify because many of these pathways are composed of redundant, sometimes, overlapping enzymes and proteins with tissue specific distributions.

Identification of known CDG subtypes and new causative genes will certainly be enhanced by newer technologies such as high-density linkage analysis, high-throughput sequencing, and greater awareness. But in the end, CDG subtype also needs to be confirmed biochemically.

Understanding the role of sugar chains in building cell-surface signaling complexes and finding how to boost sugar donors in cells may help to understand and treat these pathologies. Interactions among basic scientists focused on glycobiology and glycosylation-savvy clinicians will be the key to further discoveries.

Glossary

Endoplasmic reticulum (ER) Intracellular meshwork of membranes in eukaryotic cells; the ER is endowed with the ability to synthesize lipids and is a departure point for the transport of proteins to the cell surface and extracellular space.

Glycoconjugate Macromolecule containing sugars.

Glycolipid Lipid molecule to which sugars are covalently attached.

Lipid-modified proteins Proteins, including glycosylphosphatidylinositol (GPI)-anchored proteins, to which lipids (fatty acids, isoprenoids, or GPI) are covalently attached.

Phospholipid Amphipathic molecule with a hydrophobic tail consisting typically of two fatty acids linked to glycerol, and a hydrophilic head also attached to a glycerol backbone.

Glycosylphosphatidylinositol (GPI)-anchored proteins are a class of lipid-anchored membrane proteins that are ubiquitously expressed at the surface of eukaryotic cells. GPI proteins represent roughly 1% of all proteins encoded by eukaryotic genomes. They differ from traditional membrane proteins in that they rely on a complex glycolipid, GPI, rather than a hydrophobic transmembrane sequence for their association with membranes. GPI anchors are found on a variety of functionally diverse proteins (as well as glycoconjugates) including cell-surface receptors (folate receptor, CD14), cell adhesion molecules (neural cell adhesion molecule isoforms and carcinoembryonic antigen variants), cell surface hydrolases (5'-nucleotidase, acetylcholinesterase), complement regulatory proteins (decay accelerating factor), and protozoal surface molecules (*Trypanosoma brucei* variant surface glycoprotein, *Leishmania* lipophosphoglycan). Along with serving to attach proteins to the cell surface, GPI-anchored proteins appear to be markers and major constituents of detergent-resistant lipid rafts, the sphingolipid- and sterol-rich domains in membranes that are postulated to play an important role in the activation of signaling cascades.

GPI Structure

The structure of a GPI-anchored protein is shown in [Figure 1](#). The carboxy terminus of the protein is linked via an ethanolamine residue to GPI. The core GPI structure consists of ethanolamine phosphate linked via a linear sequence of three mannose residues and a single glucosamine residue to the phospholipid phosphatidylinositol (PI).

GPI Biosynthesis

Outline of the Biosynthetic Pathway

The GPI structure is assembled in the endoplasmic reticulum (ER) via a complex metabolic pathway composed of at least 10 steps and requiring the participation of at least 20 distinct gene products. Synthesis occurs by sequential addition of monosaccharides to PI yielding the core GPI structure that is then added to proteins. [Figure 2](#) illustrates the sequence of reactions involved in the assembly of a GPI protein anchor precursor in mammalian cells; variations of this general sequence are found in all

organisms studied thus far. GPI biosynthesis is initiated on the cytoplasmic face of the ER via the addition of *N*-acetylglucosamine (GlcNAc) from UDP-GlcNAc to PI yielding GlcNAc-PI ([Figure 2](#), step 1). The enzyme that catalyzes this first step is an unusual complex consisting of six membrane proteins in mammalian cells. GlcNAc-PI is subsequently de-*N*-acetylated to generate GlcN-PI ([Figure 2](#), step 2). The third step in biosynthesis is the acylation of the 2-OH of the inositol residue of GlcN-PI ([Figure 2](#), step 3). The acylation step is required prior to the addition of three mannose residues to GlcN-(acyl)PI ([Figure 2](#), step 5), and modification of the mannose residues with phosphoethanolamine (EtNP) side chains ([Figure 2](#), step 6). In contrast to the first two steps of synthesis that occur on the cytoplasmic leaflet of the ER, the mannosylation reactions are thought to occur lumenally based on the predicted membrane topology of the mannosyl transferases. This indicates that the substrate (GlcN-PI or GlcN-(acyl)PI) must be flipped across the ER membrane bilayer ([Figure 2](#), step 4). The mannose and EtNP residues are derived from lipids. Dolichol-P-mannose serves as the mannose donor for all three mannosylation steps and EtNP residues are added from the phospholipid phosphatidylethanolamine. The terminal EtNP residue is critical, since it is this residue that is involved in the linkage of GPI to the carboxy terminus of proteins ([Figure 2](#), step 7). Fully assembled GPI structures, or the GPI moiety in GPI-anchored proteins, are frequently subject to lipid remodeling reactions in which fatty acids or the entire lipid moiety is replaced with different fatty acids or lipids.

GPI Attachment to Proteins

Newly synthesized proteins are attached to pre-existing GPIs in the lumenal leaflet of the ER by a GPI:protein transamidase complex. Proteins to be GPI-anchored contain an N-terminal signal sequence that targets them to the ER and a C-terminal signal sequence that directs GPI anchoring. The N-terminal signal sequence is cleaved by signal peptidase during or after translocation of the nascent polypeptide into the ER lumen. The C-terminal GPI signal sequence is then cleaved and replaced with a GPI anchor through the action of GPI transamidase.

The C-terminal GPI-signal peptide, which is cleaved at what is referred to as the ω site, is necessary and sufficient for designating that a protein becomes GPI anchored. The GPI

Figure 1 The top schematic illustrates different membrane and membrane-associated proteins in the cell-surface membrane of a eukaryotic cell (internal membranes of the cell are not shown). Proteins containing hydrophobic stretches of amino acids may span the membrane once (monotopic membrane proteins) or several times (polytopic). GPI-anchored proteins are firmly associated with the cell-surface membrane, but confined to the outer leaflet of the membrane bilayer since the anchor cannot span the membrane. Other lipid-anchored proteins (such as N-myristoylated, palmitoylated, and prenylated proteins) are attached to the cytoplasmic leaflet of the cell-surface membrane. GPIs attached to protein have the conserved structure shown in the lower part of the figure. Variations of the structure include substituents on each of the mannose residues (phosphoethanolamine groups, monosaccharides, etc.; indicated R1–R6), differences in the lipid moiety (diacylglycerol, alkylacylglycerol, ceramide, etc.), and the presence of a fatty acyl chain attached to the 2-position of the myo-inositol ring. From Ferguson MAJ, Brimacombe JS, Brown JR, *et al.* (1999) The GPI biosynthetic pathway as a therapeutic target for African sleeping sickness. *Biochimica et Biophysica Acta* 1455: 327–340.

Figure 2 GPI biosynthesis in the ER. The pathway is a simplified version of the biosynthetic process in mammalian cells and is broadly similar in all other eukaryotic organisms. Biosynthesis is initiated on the cytoplasmic face of the ER by the transfer of GlcNAc from UDPGlcNAc to PI (step 1). GlcNAc-PI is de-N-acetylated (step 2), then acylated on the inositol residue (step 3) to yield GlcN-acyl PI. This lipid is flipped across the ER membrane (step 4), triply mannosylated (step 5) (dolichol-phosphate-mannose (Dol-P-Man) contributes each of the mannose residues) and capped with a phosphoethanolamine residue (step 6) (donated by the phospholipid phosphatidylethanolamine (PE)). Other phosphoethanolamine residues may also be added, some prior to the completion of mannosylation. It is possible that step 3 occurs in the ER lumen and that GlcN-PI, rather than GlcN-acyl PI is flipped across the ER membrane. The mature GPI structure is then attached to ER-translocated proteins bearing a C-terminal, GPI-directing signal sequence, to yield a GPI-anchored protein (step 7).

transamidase complex responsible for attaching the protein to the GPI anchor consists of at least five subunits. The enzyme recognizes a protein containing a GPI-anchoring signal sequence, then cleaves the signal sequence and attaches the new carboxy terminus to the terminal EtNP of a pre-existing GPI.

GPI Anchoring in Mammals, Parasitic Protozoa, and Yeast

GPI-deficient mammalian cells are viable in tissue culture, but a GPI defect has clear consequences for multicellular organisms. Transgenic mouse embryos lacking the ability to

initiate GPI biosynthesis (defective in PIG-A) do not develop beyond the ninth day of gestation. The inability of certain blood cells to express GPI-anchored proteins results in the rare human disease, paroxysmal nocturnal hemoglobinuria (PNH), characterized by intravascular hemolysis, thrombosis, and bone marrow failure. The disease is caused by a somatic mutation of the X-linked PIG-A gene (encoding the catalytic component of the enzyme responsible for the first step in GPI biosynthesis) in hematopoietic stem cells. Cells defective in PIG-A either are unable to synthesize GPIs or exhibit a significant decrease in the synthesis of GPIs and thus decreased expression of GPI-anchored proteins. Red blood cells no longer expressing GPI-anchored complement regulatory proteins

(e.g., CD55 and CD59) become susceptible to complement-mediated lysis, resulting in the release of heme and hemoglobin into the blood, filtering by the kidney, and excretion in the urine. Interestingly, while the GPI-deficient phenotype of hematopoietic stem cells makes the cells more sensitive to complement-mediated lysis, the defective PNH clone still persists. This implies that there must be other factors that select for clonal expansion and maintenance of GPI-deficient blood cells. One proposal is that PNH patients possess autoreactive T cells that target GPI on the surface of hematopoietic stem cells; thus, PNH cells would evade damage because they lack surface GPI molecules.

GPI anchoring is the most prominent mode of attachment for cell-surface proteins and glycans in parasitic protozoa. Pathogenic protozoa, including species of the genera *Trypanosoma*, *Leishmania*, and *Plasmodium*, display abundant GPI-anchored cell-surface macromolecules that play crucial roles in parasite infectivity and survival. An example is the GPI-anchored variant surface glycoprotein of bloodstream forms of *Trypanosoma brucei*, the causative agent of African sleeping sickness.

GPIs serve a unique function in yeast (*Saccharomyces cerevisiae*). In addition to anchoring secretory proteins to the cell surface, GPIs play an additional role in yeast cell-wall biosynthesis. The yeast cell wall consists of a fibrous lattice of mannoproteins, β 1,3-glucan, β 1,6-glucan, and chitin. During cell-wall biosynthesis, GPI-anchored mannoproteins are transported through the secretory pathway to the cell surface. After arrival at the plasma membrane, a transglycosylation reaction results in cleavage of the GPI moiety between GlcN and the first mannose residue and formation of a glycosidic linkage between the mannoprotein-GPI-remnant and β 1,6 glucan. Mutations in GPI biosynthesis are lethal in yeast and decreased levels of GPI biosynthesis cause growth defects and aberrant cell-wall biogenesis. However, not all GPI-anchored proteins become cross-linked to β 1,6 glucan; the amino acids within four or five residues upstream of the ω site determine whether the protein becomes incorporated into the cell wall or remains anchored to the plasma membrane. A unique characteristic of yeast GPIs is the addition of a fourth mannose residue to the core GPI structure (via an α 1–2 linkage to the third mannose). Most GPI-anchored proteins in yeast also undergo lipid remodeling, replacing the glycerolipid backbone with ceramide. The remodeling occurs after the attachment of protein to the GPI and can occur in both the ER and the Golgi.

Functions of GPIs

GPIs function as membrane anchors for secretory proteins and are believed to provide targeting signals that influence the intracellular trafficking of these proteins. GPI-anchored proteins have been shown to coalesce with sphingolipids and cholesterol into detergent-insoluble membrane domains, or lipid rafts. Association of molecules in rafts at the plasma membrane, including GPI-anchored proteins (in the exoplasmic

leaflet) and acylated signaling molecules (in the cytoplasmic leaflet), is postulated to play an important role in the activation of signaling cascades. In some polarized epithelial cells, GPI-anchored proteins and many glycosphingolipids are sorted in the *trans*-Golgi network and specifically targeted to the apical membrane. Once at the plasma membrane, GPI-anchored proteins can undergo endocytosis and recycling back to the cell surface. However, uptake of GPI-anchored proteins is $\sim$ 5 times slower than that of receptor-mediated endocytosis and recycling to the plasma membrane is $\sim$ 3 times slower than that of recycling receptors. The current view is that GPI anchoring of proteins directs their segregation into lipid rafts and affects their sorting in both the exocytic and endocytic pathways. A GPI anchor may also allow a protein to be selectively released from the cell surface upon hydrolysis by a GPI-specific phospholipase (e.g., PI-PLC or GPI-PLD) or to transfer between cells and stably insert in the external leaflet of the acceptor cell's plasma membrane. Although the biological significance of this latter phenomenon is unclear, however, the ability of GPI-anchored proteins to transfer between cells has implications for the expression of foreign proteins on the cell surface.

Glossary

Cisternae Flattened membrane-limited structures that stack together to form the Golgi complex.

Coatomer A seven-subunit transport vesicle protein coat complex involved in trafficking at the Golgi complex.

Endoprotease An enzyme that cleaves a protein into two or more fragments.

Glycoprotein A protein that is attached to complex sugar molecules called 'oligosaccharides'.

Golgi matrix A protein network that binds to the cytosolic face of Golgi cisternae and contributes to Golgi morphology and positioning.

Golgin A large family of rod-shaped proteins that bind to the cytosolic face of Golgi membranes. Golgins contribute to the formation of the stacked ribbon-like morphology.

Secretory vesicles Specialized transport vesicles that transport proteins from the *trans*-Golgi network to the plasma membrane. These vesicles can sometimes be regulated to allow release of proteins such as hormones from cells only under certain conditions.

Transport vesicle A small spherical structure that mediates protein transport between organelles. It is formed by the assembly of a protein coat.

The Golgi complex or Golgi apparatus is an organelle of eukaryotic cells involved in the processing and transport of proteins. The Golgi complex is one of a group of cellular organelles including the endoplasmic reticulum, endosomes, and lysosomes that compose the secretory and endocytic pathways. Proteins are transported through the organelles of the secretory pathway en route to the plasma membrane for secretion into the extracellular space or insertion into the membrane. This pathway also transports and sorts the resident proteins of many cellular organelles. Secreted proteins such as hormones enter the secretory pathway by translocation into the endoplasmic reticulum. They are then concentrated and transported via vesicle intermediates to the Golgi complex. At the Golgi complex, proteins can undergo processing events such as proteolytic cleavage and the removal or addition of sugar moieties. Proteins are finally sorted into various classes of post-Golgi vesicles for transport to the proper location in the cell. Hence, the Golgi complex plays a central role in the function of the secretory pathway and is the subject of intense investigation by cell biologists. Although important aspects of Golgi function remain to be fully characterized, previous studies have revealed many interesting features of its morphology and its role in the transport and processing of proteins.

Morphology of the Golgi Complex

The Golgi complex is often found as a set of three to five stacked saccules or cisternae (Figure 1(a)). The cisternae are organized with a polarity such that there is a *cis*-cisterna where proteins arriving from the endoplasmic reticulum enter and a *trans*-cisterna where proteins exit the Golgi complex. Proteins pass through the medial cisternae that are present between the *cis*- and *trans*-cisternae. The *cis*- and *trans*-faces of the Golgi apparatus are often reticulated and thus referred to as the *cis*-Golgi network and the *trans*-Golgi network. Although most eukaryotic cells have stacked Golgi cisternae, this configuration is not universal. For example, brewer's yeast, *Saccharomyces cerevisiae*,

has distinct *cis*-, medial-, and *trans*-Golgi cisternae that remain dispersed from each other in the cytoplasm.

Stacked Golgi Morphology Is Conferred by the Golgin Proteins

Golgins are rod-shaped proteins that localize to the Golgi apparatus in all eukaryotic cells. They play important roles in establishing and maintaining Golgi morphology. The Golgi reassembly and stacking proteins, GRASPs, are golgins that contribute to the stacked morphology observed in most eukaryotes. Vertebrates have two GRASP proteins, GRASP55 and GRASP65, that assemble into membrane-bound oligomers that then tether the individual cisternae into stacks. GM130 is another golgin protein that acts as a tether to assist with Golgi stacking and binding interactions between transport vesicles and the cisternal membrane.

Golgins are also known to be components of the Golgi matrix, an assembly of peripheral membrane-binding proteins that contribute to Golgi morphology. The Golgi matrix persists near the nucleus even when membrane components of the Golgi complex are removed. In vertebrate cells, the Golgi matrix can be observed by electron microscopy as a region surrounding the Golgi apparatus from which cytosolic ribosomes are excluded.

Golgin proteins of the Golgi matrix and the Golgi membranes are regulated by the Rab family of guanosine triphosphate (GTP)-binding proteins. Rabs comprise a large protein family that regulates many aspects of vesicular trafficking, membrane fusion, and organelle morphology. There are over 15 Rab proteins that localize to the Golgi apparatus in mammalian cells.

The Subcellular Localization of Golgi Complexes

The subcellular distribution of the Golgi complex varies among eukaryotic organisms. In plants and invertebrates the stacked Golgi complexes are typically dispersed throughout the cell. In these cell types, the dispersed Golgi membranes are often positioned near transport-vesicle-exit sites on the endoplasmic

Figure 1 The morphology and localization of the mammalian Golgi complex. (a) A transmission electron micrograph of a Golgi complex from a rat kidney cell. Note that it is composed of three stacked cisternae: *cis*, medial, and *trans*. Transport vesicles are apparent near the Golgi complex as circular profiles. (b) A fluorescence micrograph of normal rat kidney cells that are decorated with an antibody against the Golgi enzyme, mannosidase II. Note that the labeled Golgi stacks (red) are concentrated in a region next to the cell nucleus.

reticulum. The Golgi complex in plants is dispersed through cytoplasmic streaming that results from myosin motor-based motility along actin microfilaments. In vertebrate cells, the stacked Golgi complexes are frequently localized together at a single site adjacent to the cell nucleus (**Figure 1(b)**). This site is near the centrosome, a cellular structure involved in the assembly and organization of microtubules, which are one of the key components of the cell cytoskeleton. In mammalian cells, the juxtanuclear localization of the Golgi complex involves the translocation of pre-Golgi vesicles along microtubules using a molecular motor protein called 'dynein'. Dynein motor protein also plays a role in organizing the Golgi cisternae into the interconnected ribbon-like structures.

Golgi positioning is related to cell polarity

In polarized cells of vertebrates, such as intestinal epithelial cells, the Golgi complex is localized in a polarized manner between the nucleus and the apical cell surface. Similarly, the Golgi apparatus is localized between the nucleus and the leading edge of motile cells. The advantage of maintaining a compact Golgi complex adjacent to the nucleus in vertebrate cells is still not fully understood, but it is likely to facilitate the polarized delivery of post-Golgi transport vesicles toward sites of rapid membrane growth such as the leading edge of a motile cell.

The Vertebrate Golgi Apparatus Serves as a Microtubule-Organizing Center

The morphology and positioning of the Golgi apparatus in vertebrate cells are highly dependent on the microtubule cytoskeleton. There are only a few sites called 'microtubule-organizing centers' where microtubule assembly is initiated in cells. By contrast, actin microfilament assembly can be initiated at many different sites within the cell and at the plasma membrane. Historically, the nucleation of new microtubules was thought to be restricted to the centrosomes and

basal bodies, cellular structures characterized by the presence of centrioles. It is now clear the Golgi complex is also able to nucleate microtubule assembly. Both centrosomes and Golgi membranes nucleate microtubules through a mechanism that requires the gamma-tubulin ring complex, γ -TURC. Nevertheless, Golgi-derived and centrosome-derived microtubules are distinct from each other. Golgi-derived microtubules are able to bind to distinct isoforms of the cytoplasmic linker associated protein (CLASP) family of microtubule plus-end-binding proteins. One role for the Golgi-apparatus-derived microtubules is to establish membrane connections between Golgi stacks and maintain the ribbon-like morphology. Although there is variability in the morphology and organization of the Golgi complex among eukaryotic cells, in all cases, the Golgi is a critical site for processing and sorting of proteins that are transiting the secretory pathway.

Protein Processing in the Golgi Complex

Protein Glycosylation

Many proteins, especially those localized to the cell surface, are covalently attached to complex sugar moieties called 'oligosaccharides' to form glycoproteins. One of the best-characterized functions for the Golgi apparatus is in the addition and modification of oligosaccharides on glycoproteins. Many proteins are modified at specific asparagine amino acid residues in the endoplasmic reticulum in a process called 'N-linked glycosylation', which is carried out by the enzyme oligosaccharyl transferase. In the Golgi complex, additional oligosaccharide chains can be attached to certain serine or threonine amino acid residues via the enzyme peptidyl N-acetylgalactosamine-transferase. This process is referred to as 'O-linked glycosylation'. Both N-linked and O-linked oligosaccharides are further modified in the Golgi complex through both the removal and addition of specific sugars. The processing of N-linked oligosaccharides by the Golgi complex is understood in some detail. In the Golgi complex, mannose is trimmed from N-linked oligosaccharides through the action of mannosidase II. This is followed by the addition of N-acetylglucosamine, galactose, and sialic acid by sugar-specific transferases. The enzymes that catalyze the various processing steps are spatially organized throughout the Golgi stacks in the order in which they function. For example, N-acetylglucosamine transferase is mostly enriched in the *cis*-Golgi cisterna, while sialic acid transferase is found predominantly in the *trans*-cisterna. The role of protein glycosylation is still not fully understood, but one described function includes protein sorting.

Proteolytic Processing

Some proteins must be cleaved within the secretory pathway before they are functional. Examples of such proteins include various proteases, hormones, and transcription factors.

Prohormone processing

Many peptide hormones are first synthesized as part of a larger inactive polypeptide, which is then cleaved by enzymes called 'endoproteases' into a smaller active form. For example, the metabolic hormone, insulin, folds first as a long polypeptide,

which is then cleaved at two sites releasing an inactive fragment, the C-peptide, to form the fully active insulin molecule. Many of these proteolytic processing steps occur in the *trans*-Golgi network and in post-Golgi secretory vesicles. The endoproteases that carry out this processing are generally referred to as prohormone convertases. One *trans*-Golgi-network-localized endoprotease, furin, has been extensively characterized and is involved in processing a wide variety of receptors and hormones.

Proteolytic regulation of transcription factors

Regulation of a transcription factor involved in cholesterol metabolism

In some cases, Golgi-localized endoproteases are used for the activation of proteins that function as part of regulatory signaling pathways. A very interesting example of this type of regulation is the proteolytic activation of sterol-response-element-binding protein (SREBP). SREBP is a transcription factor that activates genes that are involved in cholesterol uptake and biosynthesis. It resides as an integral membrane protein on the endoplasmic reticulum when cellular cholesterol levels are elevated. However, when cholesterol levels in the cell are low, SREBP is transported out of the endoplasmic reticulum to the Golgi complex where it is cleaved by two endoproteases. One of these enzymes is unique since it cleaves the transmembrane domain of SREBP within the plane of the membrane. The result of this proteolysis in the Golgi complex is the release of an active transcription factor from the membrane, which is then translocated into the nucleus to activate genes involved in sterol metabolism.

A Golgi-localized endoprotease is involved in Alzheimer's disease

The toxic peptide β -amyloid accumulates in plaques found within the brain of individuals with Alzheimer's disease. β -Amyloid is generated through inappropriate proteolytic cleavage of amyloid precursor protein. A Golgi-localized endoprotease called 'presenilin' is important for normal processing of amyloid precursor protein. Presenilin is similar to the Golgi-localized endoprotease that activates SREBP since it cleaves the amyloid precursor protein within the membrane.

The examples of endoprotease function described here are illustrative of the wide variety of proteins and cellular processes that utilize proteolytic processing at the Golgi complex.

Mechanisms of Protein Transport at the Golgi Complex

Vesicular Transport at the Golgi Complex

One important mechanism for moving proteins and phospholipids to, from, and within the Golgi complex is via transport vesicles. These small, spherical, membrane-limited structures are formed on organelles through the assembly of a protein coat. The coat deforms the membrane into a vesicle and plays a role in selecting the appropriate cargo proteins. Once formed, the vesicles are translocated to the target organelle where they fuse with the membrane and deliver their contents. Several types of transport vesicles, each with a distinct protein coat, function at the Golgi complex. Two well-studied examples are clathrin-coated vesicles that mediate transport of proteins leaving the *trans*-Golgi network, and coat-protomer I (COPI)

vesicles that mediate transport among the cisternae and backwards transport out of the Golgi complex.

The clathrin complex binds to membranes via adaptor proteins during the formation of transport vesicles. The clathrin adaptor proteins adaptor protein 1 (AP-1) and Golgi-localized, gamma adaptin ear-containing, ARF binding (GGA) that bind to the *trans*-Golgi network for anterograde post-Golgi trafficking are distinct from the AP-2 adaptor protein used for clathrin-mediated endocytosis from the plasma membrane. COPI vesicles form on Golgi membranes using the seven-subunit protein complex called 'coatamer'. The recruitment of both clathrin adaptors and coatamer is regulated by the small GTP-binding protein called 'ARF' (ADP-ribosylation factor). The ARF1 isoform localizes at the Golgi apparatus and can trigger the assembly of both clathrin and COPI vesicles. The GTP exchange reaction that activates ARF1 is inhibited by the fungal metabolite brefeldin A. Brefeldin A is commonly used in experimental cell biology to study the consequences of disrupting the secretory pathway.

Cisternal Progression

A second mechanism for moving proteins through the Golgi complex is cisternal progression. Here, the *cis*-cisternae are transformed into medial cisternae, and medial cisternae are transformed into *trans*-cisternae. New *cis*-cisternae are created by vesicles arriving from the endoplasmic reticulum. The *trans*-cisternae are expended by the formation of transport vesicles involved in post-Golgi trafficking. Progressive changes in the repertoire enzymes within the cisternae occur through vesicle-mediated protein transport and sorting of the resident Golgi proteins. During cisternal progression, forward-moving cargo proteins are carried along with the cisternae as they progress from the *cis* to medial to *trans* positions.

Protein Sorting at the Golgi Complex

Proteins must be properly sorted and targeted as they traverse and exit the Golgi complex. At the *trans*-Golgi network, proteins are destined for several different locations. Many proteins are sent to the cell surface for insertion into the plasma membrane or for release into the extracellular space. Other proteins must be targeted to intracellular organelles such as late endosomes or lysosomes. In addition to the sorting of forward-moving proteins, some proteins are retrieved or recycled back to earlier compartments. For example, proteins that function within the Golgi complex are recognized and retained at or retrieved to the proper cisterna. Two sorting mechanisms that have been characterized at the Golgi complex are receptor-mediated packaging into transport vesicles and protein aggregation.

Receptor-mediated sorting into transport vesicles

A key aspect of protein sorting throughout the secretory pathway is the selective packaging of cargo proteins into transport vesicles. This involves either direct or indirect (receptor-mediated) interactions with the vesicle-coat proteins. Thus, a vesicle targeted for a specific organelle in the cell can select cargo proteins that are destined for the same location. Discussed next are two receptor proteins that function in cargo selection during protein transport from the Golgi complex, namely the mannose-6-phosphate receptor and the KDEL receptor.

The mannose-6-phosphate receptor

The mannose-6-phosphate receptor sorts proteins into clathrin-coated vesicles that are leaving the *trans*-Golgi network and are destined for organelles called lysosomes involved in breaking down cellular waste products. Mannose-6-phosphate is an N-linked oligosaccharide generated by enzymes present in the *cis*-Golgi cisterna. It is formed specifically on proteins destined for the lysosome. The mannose-6-phosphate receptor spans the Golgi membrane and binds to coat proteins on the cytosolic side of the membrane and to the mannose-6-phosphate-containing protein on the luminal side of the membrane. Thus, mannose-6-phosphate-containing proteins are sorted and concentrated into the correct clathrin-coated vesicles for transport to the lysosome.

The KDEL receptor

Many resident proteins of the endoplasmic reticulum are retrieved from the Golgi complex if they escape. The KDEL receptor functions in this retrieval process by sorting proteins that belong in the endoplasmic reticulum into COPI vesicles for backwards transport. KDEL refers to the single-letter code for the amino acid residues lysine, aspartic acid, glutamic acid, and leucine, which are present on many endoplasmic reticulum-resident proteins. Similar to the mannose-6-phosphate receptor, the KDEL receptor binds to COPI-coat proteins on the cytosolic side of the membrane and to KDEL-containing protein on the luminal side. This allows for sorting and retrieval of endoplasmic reticulum-localized proteins via COPI vesicles.

Protein aggregation as a sorting mechanism

Another way that proteins are sorted in the Golgi complex is through aggregation. Some resident Golgi proteins, such as the enzyme mannosidase II, form aggregates with themselves and other Golgi-resident proteins. Golgi proteins may be retained at the proper cisternae through the exclusion of the large aggregates from transport vesicles. By contrast, some proteins – for example, insulin and many other hormones – may cluster within the *trans*-Golgi network to facilitate their concentration and packaging into vesicles. Aggregation continues in the secretory vesicles before its delivery to the plasma membrane and release into the extracellular space.

The Golgi Cisternae Serve as an Intracellular Calcium Store

Together with the endoplasmic reticulum and mitochondria, the Golgi apparatus acts as a calcium store. The spatially and temporally regulated release of calcium from intracellular stores contributes to a broad range of cellular signaling observed in all eukaryotes including plants, fungi, and vertebrates. Cell metabolism, hormone secretion, and neuronal transmission are a few examples of processes that are regulated by agonist-triggered release of calcium. Calcium enters the lumen of Golgi cisternae through the action of adenosine triphosphate (ATP)-dependent pump proteins. Golgi-specific members of the sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA)-family are one class of proteins that pump calcium into the Golgi lumen. A second family of Golgi pump proteins belong to the secretory-pathway calcium ATPase (SPCA) family that catalyzes the active transport of both

calcium and manganese ions. PMR1 is an example of a Golgi-specific SPCA pump that has been characterized in yeast. Calcium is buffered in the lumen of the Golgi apparatus by Golgi-specific calcium-binding proteins such as CALNUP. Calcium release is triggered from both the Golgi apparatus and the endoplasmic reticulum by the second messenger inositol trisphosphate (IP₃). IP₃ binds to calcium-specific channel proteins, allowing calcium to exit the Golgi lumen into the cytosol.

The familial skin disorder, Hailey–Hailey disease, occurs in humans with only one allele of the Golgi calcium pump SPCA1. Hailey–Hailey disease is characterized by skin blistering and erosion. The disruptions in intracellular calcium dynamics that occur from decreased calcium ATPase activity at the Golgi complex causes defects in cell adhesion among skin keratinocytes leading to the painful disease phenotypes.

Summary

The Golgi apparatus plays a central role in the function of the secretory pathway. In eukaryotic cells, thousands of proteins can be properly transported, processed, and sorted as they move through the Golgi complex. The Golgi complex adopts a complex morphology and can be precisely positioned to carry out these tasks. The ability of the Golgi apparatus to act as a microtubule-organizing center and the complex connections between Golgi stacks to form the stacked ribbon-like morphology are recently studied features of the Golgi. Future studies by cell biologists are certain to uncover unexpected features of this complex cellular organelle at the center of the secretory pathway.

The GRK Family

GRKs specifically phosphorylate activated GPCRs and initiate the recruitment of arrestins, which mediate receptor desensitization, endocytosis, and downregulation (Figure 1). GRKs are serine/threonine protein kinases found in metazoans. In mammals, there are seven GRKs that can be divided into three subfamilies based on overall structural organization and homology: GRK1 (also termed 'rhodopsin kinase') and GRK7; GRK2 (β ARK1) and GRK3 (β ARK2); and GRK4, GRK5, and GRK6. GRK1 and 7 are expressed in visual rod and cone cells, respectively, GRK4 is primarily expressed in testes, kidney, and brain, and GRK2, 3, 5, and 6 are ubiquitously expressed. *Drosophila melanogaster* (GPRK1 and GPRK2) and *Caenorhabditis elegans* (GRK-1 and GRK-2) each express a GRK2 (GPRK1 and GRK-2) and GRK4 (GPRK2 and GRK-1) subfamily ortholog.

GRKs have a tripartite modular structure. A central ~330 amino acid catalytic domain, most related to those of other AGC kinases such as PKA and PKC is flanked by an ~180 residue N-terminal region that contains a regulator of G-protein signaling homology (RH) domain, and an ~80–180 amino acid C-terminal lipid-binding domain that varies in structure (Figure 2(a)).

Role of GRKs in GPCR Regulation

GRKs specifically phosphorylate agonist-occupied GPCRs and initiate the process of desensitization. While no clear consensus sequence for GRK-mediated phosphorylation has been identified, specific sites for GRK-mediated phosphorylation have been mapped to either the carboxyl-terminal tail or the third intracellular loop of many GPCRs. A wide variety of strategies have been used to define the specificity of GPCR phosphorylation by GRKs including *in vitro* analysis as well as intact cell studies using overexpression, dominant negative mutants, inhibitory antibodies, antisense constructs, and RNA interference. While these efforts have started to dissect the specificity of GRK/GPCR interaction, the fact that most cell lines express a large number of GPCRs as well as several GRKs makes it virtually impossible to completely define such specificity. Nevertheless, some receptors appear to be primarily phosphorylated by a single GRK while others are regulated by multiple GRKs in a cell-type-dependent manner.

Insight into GRK specificity/function has also been gained from *in vivo* strategies. For example, transgenic mice with cardiac-specific overexpression of GRK2 lead to increased desensitization of the β -adrenergic receptor (β AR) and an associated decrease in left ventricular contractility while mice overexpressing a GRK2 inhibitor demonstrate increased left ventricular contractility even in the absence of β -agonist. Cardiac-specific overexpression of GRK5 in transgenic mice has a similar effect on β AR-mediated signaling

and contractility, while the angiotensin II-mediated contractile response is attenuated only in the GRK2-overexpressing mice. Further demonstration of specificity is suggested in transgenic mice with myocardial overexpression of GRK3 where no effect on β AR response is observed. Moreover, studies involving cardiac overexpression of individual GRKs in mice revealed that GRK3 > GRK5 > GRK2 at desensitizing α_{1B} -adrenergic receptor signaling in the heart. These studies suggest some level of GRK specificity is evident *in vivo* even when the GRKs are overexpressed.

Perhaps the most insight into GRK specificity and function has been gained from functional knock-outs. GRK1 knock-out mice have a prolonged response to light and undergo apoptotic retinal degeneration due to the loss of rhodopsin phosphorylation and also have a slowed cone recovery. Disruption of the GRK2 gene in mice results in embryonic lethality as a consequence of hypoplasia of the ventricular myocardium, suggesting a role for GRK2 in cardiac development, although studies that selectively ablated GRK2 in cardiomyocytes produced viable mice with a normal heart structure and function. Disruption of the mouse GRK3 gene results in normal development and physiology, although specific defects in desensitization of odorant-induced cyclic adenosine monophosphate (cAMP) responses in olfactory epithelium, cholinergic response of airway smooth muscle, and κ -opioid receptor-mediated responses are observed. A GRK4 knock-out mouse exhibits no obvious phenotypes while a GRK5 knockout results in muscarinic supersensitivity and impaired receptor desensitization in the lung but not in the heart. Disruption of the GRK6 gene results in altered CXCL12-promoted chemotaxis of lymphocytes, supersensitivity to the locomotor-stimulating effects of cocaine and amphetamine, and enhanced coupling of postsynaptic D2-like dopamine receptors.

GRKs have also been characterized in lower eukaryotic animals. For example, a mutation that disrupts expression of GPRK2 leads to specific defects in *Drosophila* embryogenesis, possibly due to a role in Hedgehog signaling, while defects in Hedgehog signaling are also observed with knockdown of GRK2/3 in zebrafish. A mutation that results in reduced activity of GRK-2 in *C. elegans* results in a defect in chemosensory responses. Taken together, these findings reveal that GRKs are involved not only in regulating signaling but may also have critical roles in regulating growth and development.

GRKs Have Diverse Functional Roles

While GRKs specifically phosphorylate activated GPCRs, they also phosphorylate a variety of other proteins including Smoothed, the epidermal growth factor (EGF) and platelet-derived growth factor (PDGF) receptors, tubulin, synucleins, phosphodiesterase γ (PDE γ), phosphducin, ezrin, R-Smads, downstream

Figure 1 Schematic representation of GPCR trafficking. Agonist-activated receptors are phosphorylated by a GRK leading to the recruitment of arrestins. Arrestins serve as adaptor proteins by virtue of their ability to link receptors to components of the transport machinery such as clathrin, AP-2, and phosphoinositides leading to internalization. Additional interactions with GRKs and arrestins appear to play a role in this process. Once in endosomes, recycling receptors (recycling pathway) are readily segregated from receptors destined for lysosomes (degradation pathway). Although poorly understood, the sorting decision may be regulated by specific and distinct protein interactions or modification by ubiquitin. Receptors that enter the recycling pathway are sorted into recycling endosomes and traffic back to the cell surface resulting in resensitization. Receptors that enter the degradation pathway are trafficked to lysosomes where they are proteolyzed leading to a loss in the total cellular complement of the receptor, a process known as 'downregulation'. Internalized GPCR–arrestin complexes have also been shown to regulate intracellular signaling pathways such as MAP kinases.

Figure 2 The structure of GRK. (a) Schematic representation of the GRK structure. GRKs have a conserved regulator of G-protein signaling homology (RH) domain (shown in blue). The conserved catalytic domain is shown in red. In yellow is the C-terminal domain: GRK2 and GRK3 possess pleckstrin homology (PH) domain whereas GRK5 contains a polybasic region involved in phospholipid binding. Other GRKs are posttranslationally modified: GRK1 is farnesylated, GRK4 and 6 are palmitoylated, and GRK7 is geranylgeranylated. (b) Crystal structure of GRK2. The structure was solved as part of the G_{α_q} -GRK2- $G_{\beta\gamma}$ complex. The RH domain is shown in blue, the catalytic domain in red, and the PH domain in yellow.

regulatory element antagonist modulator (DREAM), histone deacetylase 5 (HDAC5), arrestin2, p38, p53, p105, and I κ B α (Table 1). The ability of GRK2 to phosphorylate Smoothed appears to regulate arrestin binding and function in a positive manner in Hedgehog signaling while GRK2 and GRK5 can phosphorylate and desensitize the PDGF receptor in a cell-type-dependent manner. GRK2 phosphorylation of ezrin, a protein involved in cytoskeletal reorganization, has been linked to β_2 AR endocytosis. The synucleins serve as effective

GRK substrates *in vitro* and in cells although it is currently unclear whether GRKs regulate synuclein phosphorylation *in vivo*. GRK2 has also been shown to phosphorylate Thr-123 in p38 resulting in inhibition of p38 activity while GRK2 phosphorylation of DREAM at Ser-95 attenuates expression of the Kv4.2 potassium channel. GRK2 can also phosphorylate R-Smads upon transforming growth factor β (TGF- β) stimulation resulting in inhibition of TGF- β signaling. Phosducin and phosducin-like protein are both phosphorylated by GRK2 *in vitro* resulting in a reduced

Table 1 GRK non-GPCR substrates and interacting targets

Target	GRK subtype	Functional role
<i>Substrates^a</i>		
Arrestin2	GRK5 > GRK2	Phosphorylation inhibits G-protein-independent ERK1/2 signaling downstream of the 5-HT ₄ receptor
DREAM	GRK2 > GRK6	Phosphorylation reduces membrane expression of Kv4 potassium channels
EGFR	GRK2	Unknown
Ezrin	GRK2	Phosphorylation regulates actin rearrangement and receptor internalization
HDAC5	GRK5	Phosphorylation regulates the transcription factor MEF2 and alters gene transcription
NF κ B1 p105	GRK5 > GRK2	Enhances phosphorylation by I κ B kinases, thus promoting p105 degradation
p38	GRK2	Reduces activation of p38 by MKK6, thus reducing p38 activity and p38-dependent cell differentiation and cytokine release
p53	GRK5	Phosphorylation regulates p53 degradation and inhibits radiation-induced apoptosis
PDE γ	GRK2	Promotes EGF- and thrombin-dependent ERK1/2 activation
PDGFR	GRK2 and GRK5	Attenuates PDGF-dependent signaling responses
Phosducin	GRK2 = GRK3 = GRK5	Reduces interaction with G $\beta\gamma$ <i>in vitro</i>
R-Smads	GRK2	Inhibits TGF β -promoted gene transcription, cell growth, and apoptosis
Smoothed	GRK2	Promotes arrestin binding and positively influences Hedgehog signaling
Synucleins	α – GRK2 = GRK5	Reduces binding to phospholipids and antagonizes PLD2 inhibition <i>in vitro</i>
(α , β , and γ)	β – GRK2 > GRK5	
	γ – GRK5 > GRK2	
Tubulin	GRK5 > GRK2 > GRK1	Unknown
<i>Interacting proteins and molecules</i>		
α -Actinin	GRK1, GRK2, and GRK5	Inhibits GRK1, GRK2, and GRK5
Actin	GRK5	Inhibits GRK5 activity
Akt	GRK2	GRK2 inhibits Akt
Caveolin	GRK2	Inhibits GRK2
Ca ²⁺ /CaM	GRK5 > GRK2	Inhibits GRK2 with IC ₅₀ = 2 μ M and GRK5 with an IC ₅₀ ~40 nM
Clathrin	GRK2	Regulates GRK2-mediated β_2 AR phosphorylation and internalization
EGFR	GRK2	Phosphorylates and activates GRK2
ERK1/2	GRK2	Inhibits GRK2 activity
G α q	GRK2	GRK2 binds and sequesters activated G α q
G $\beta\gamma$	GRK2	Recruits GRK2 to the plasma membrane
GIT1/2	GRK2	Not fully elucidated; may regulate cell migration
HSP90	GRK2, GRK3, GRK5, and GRK6	Required in GRK folding and maturation
MEK	GRK2	MEK/GRK2 interaction affects downstream signaling
NOS	GRK2	Inhibition of GRK2 by S-nitrosylation of Cys-340
Phospholipids	GRK2 and GRK5	Stimulates GRK2 and GRK5 activity
PDGFR	GRK2 and GRK5	Phosphorylates and activates GRK2 and GRK5
PI3K	GRK2	GRK2 recruits PI3K to the plasma membrane
PIP ₂	GRK2	Activates GRK2
PKA	GRK1, GRK2, and GRK7	Phosphorylates and attenuates activity of GRK1 and GRK7: enhances activity of GRK2
PKC	GRK2 and GRK5	Phosphorylation reverses Ca ²⁺ /CaM inhibition of GRK2 and inhibits GRK5 activity
PTCH1	GRK2	Regulates cell-cycle progression
Recoverin	GRK1	Inhibits GRK2 activity
RKIP	GRK2	Inhibits GRK2 activity
c-Src	GRK2	Phosphorylates and activates GRK2

^aDREAM: downstream regulatory element antagonist modulator; EGFR: epidermal growth factor receptor; ERK: extracellular signal-regulated kinase; HDAC5: histone deacetylase 5; NF κ B: nuclear factor κ B; MEF2: myocyte enhancer factor-2; MKK6: mitogen-activated protein kinase kinase 6; PDE γ : phosphodiesterase γ ; PDGFR: platelet-derived growth factor receptor; PTCH1: patched homolog 1; TGF β : transforming growth factor β ; PLD2: phospholipase D2; CaM: calmodulin; GIT1/2: G-protein-coupled receptor kinase-interacting protein 1/2; HSP90: heat shock protein 90; MEK: mitogen-activated protein kinase 1; NOS: nitric oxide synthase; PI3K: phosphoinositide 3 kinase; PIP₂: phosphatidylinositol 4,5-bisphosphate; PKA: protein kinase A; PKC: protein kinase C; RKIP: Raf kinase inhibitor protein.

ability of these proteins to bind $G\beta\gamma$ subunits. HDAC5 is a histone deacetylase that can be phosphorylated by GRK5 resulting in the inhibition of transcriptional repressor activity. GRK5 can also phosphorylate the nuclear factor κB (NF- κB) protein p105, resulting in decreased phosphorylation of p105 by $I\kappa B$ kinase (IKK) and attenuated signaling, while both GRK2 and GRK5 phosphorylate $I\kappa B\alpha$ and enhance TNF α -induced NF- κB signaling. In addition, GRK5 has recently been implicated in genome stability via the ability to phosphorylate Thr-55 in the tumor suppressor p53 and mediate p53 degradation.

While GRKs mediate many of their effects via protein phosphorylation, GRKs also interact with additional proteins and regulate their function (Table 1). For example, the N-terminal RH domain of GRK2 and GRK3 interact with and effectively inhibit $G\alpha_q$, $G\alpha_{11}$, and $G\alpha_{14}$ while GRK2 interacts with and inhibits MEK1. GRK2 also interacts with several proteins implicated in the endocytic process including clathrin, GRK interactor 1 (GIT1), and PI 3-kinase. GIT1, an ARF guanosine triphosphatase (GTPase)-activating protein, has been implicated in regulating the trafficking of receptors internalized via an arrestin- and dynamin-dependent pathway and its interaction with GRK2 may regulate cell migration. GRK2 interaction with PI 3-kinase regulates the recruitment of PI 3-kinase to the plasma membrane, where it helps modulate GPCR endocytosis. The GRK2/PI 3-kinase pathway appears to involve enhanced recruitment of AP-2 to the receptor via the increased production of D-3 phospholipids. Taken together, these studies suggest that GRKs orchestrate the formation of protein complexes that regulate receptor signaling and trafficking.

Regulation of GRK Function

A critical component in generating specificity is the molecular mechanism responsible for regulating the activity and cellular localization of GRKs. For example, phosphorylation appears to play an important role in regulating GRK activity. GRK2 phosphorylation by ERK1/2 inhibits GRK2 activity while phosphorylation by PKA, Src, PKC, and the PDGF receptor results in increased activity (Table 1). GRK5 activity is attenuated by PKC phosphorylation but stimulated by autophosphorylation and PDGF receptor phosphorylation. Interestingly, GRK2 is also inhibited by nitrosylation of a cysteine residue within the activation loop of the catalytic domain. GRK function is also regulated by interaction with additional proteins including $G\alpha$ and $\beta\gamma$ subunits, caveolin-1, tubulin and actin, Raf kinase inhibitor, and various calcium binding proteins. Phospholipids also play an important role in regulating GRK function since $G\beta\gamma$ -mediated GRK2 activation is dependent on negatively charged phospholipids including phosphatidylinositol 4,5-bisphosphate (PIP₂). Interestingly, while GRK4 subfamily members do not bind $G\beta\gamma$ subunits, these kinases share a putative amino-terminal PIP₂-binding domain that may facilitate receptor phosphorylation. These kinases also have the ability to associate with phospholipids via a carboxyl-terminal domain that is either palmitoylated (GRK4 and 6) or can directly bind phospholipids (GRK5) (Figure 2(a)). Thus, the immediate phospholipid environment may have a general and critical role in modulating GRK function.

While GRKs have been implicated in the phosphorylation of plasma-membrane-localized receptors as well as various cytoplasmic proteins, several studies reveal that some GRKs can also localize in the nucleus. GRK5 contains a nuclear localization sequence and all GRK4 family members (GRK4, 5, and 6) can localize in the nucleus. Moreover, the ability of GRK6 to localize in the nucleus appears to be regulated by its palmitoylation state. While the functional role of GRKs in the nucleus is not fully understood, a broad-based shRNA screen for proteins involved in mitotic progression identified GRK2 and GRK5 as playing a potential role in HT29 cell mitosis. Recent studies also suggest that GRK2 degradation plays an important role in regulating normal cell-cycle progression. Moreover, GRK2 interaction with patched homolog 1 (PTCH1) inhibits cyclin B1 interaction with PTCH1 and regulates the cell cycle and early development in zebrafish. Taken together, multiple mechanisms including GPCR, G protein, and phospholipid binding, post-translational modification, and intracellular localization play an important role in regulating GRK activity and function. Moreover, some GRKs may play a role in regulating nuclear events such as transcription and cell-cycle regulation.

Structural Basis of GRK Function

The X-ray crystal structures of GRK1, GRK2, GRK2/ $G\beta_1\gamma_2$, GRK2/ $G\beta_1\gamma_2$ / $G\alpha_q$, and GRK6 have provided significant insight into GRK function. Interestingly, the crystal structure of GRK2 reveals that the N-terminal RH domain, central catalytic domain, and C-terminal pleckstrin homology (PH) domain form an equilateral triangle that is ~ 80 Å on a side (Figure 2(b)). The RH domain contacts both the kinase and PH domains. Moreover, the RH domain consists of two discontinuous regions with the characteristic nine-helix bundle in the N-terminal region and two additional helices following the kinase domain. The interaction surface of GRK2 with $G\alpha_q$ primarily resides on the α_5 and α_6 helices of the RH domain. The kinase domain is most similar to that of PKA, PKB, and PDK1 but appears to be in an inactive conformation in the crystal structure. This inactive conformation is also observed in the structure of GRK6 even when bound to AMPPNP. Interestingly, the structure of the RH and kinase domain cores of GRKs appear to have similarities to the inactive structure of Src with the α_{10} helix of the RH domain potentially functioning to regulate GRK activation. Similarly, the interface between the α_4 - α_5 loop of the RH domain and the α_j helix of the kinase large lobe might also modulate GRK activity by influencing the orientation of the large and small kinase lobes. The C-terminal PH domain of GRK2 mediates phospholipid binding, primarily via the inner face of the β_1 - β_2 loop, and $G\beta\gamma$ binding via four different regions including strands β_1 - β_4 and the extended α -helix. Docking analysis of the GRK2/ $G\beta\gamma$ complex with rhodopsin as well as the co-crystal structure of GRK2/ $G\beta\gamma$ / $G\alpha_q$ suggests that the receptor, $G\alpha_q$, and $G\beta\gamma$ should be able to bind to GRK2 simultaneously. This would represent an effective way of turning off signaling by phosphorylating receptor and sequestering $G\alpha_q$ and $G\beta\gamma$ thereby preventing interaction with effector molecules.

Since the GRK catalytic domains are in an inactive conformation in the crystal structures, it is important to understand

how these enzymes are activated. Interestingly, GPCR interaction appears to regulate the catalytic activity of the GRKs. While the mechanism of this activation is unclear, there is some evidence suggesting that the GRK N-terminal region functions as a switch to regulate the activation state of the GRK. However, since the N-terminal domains of GRK1, GRK2, and GRK6 are not fully observed in the crystal structures, it is not completely understood how this region functions to regulate GRK activation.

Role of GRKs in Disease

Various experimental approaches have led to a growing appreciation of the potential pathophysiological roles of GRKs in human disease. GRK1 mutation has been identified in Oguchi's disease (a form of night blindness) while several studies have demonstrated increased expression of GRKs associated with congestive heart failure (CHF), hypertension, and myocardial ischemia. In experimentally induced models of CHF, both GRK2 and GRK5 expression and activity were enhanced two- to threefold in the left ventricular myocardium early in CHF progression. While it is not clear whether this increase in GRK levels is causal or a byproduct of elevated hormones secondary to disease, it is interesting that myocardial ischemia, which is associated with a large local release of noradrenaline, also produces a rapid increase in GRK2 messenger RNA levels. Moreover, chronic stimulation with a β AR agonist also leads to a corresponding increase in myocardial GRK2 expression in mice, while infusion of angiotensin II into the aortas of hypertensive rats induces a rapid threefold increase in GRK5 expression as well as an increase in GRK2 expression. Conversely, a reduction in β -agonist levels results in decreased myocardial GRK2 expression in mice. Interestingly, lymphocyte GRK2 levels may provide a marker of myocardial GRK2 levels as well as a diagnostic in the treatment of heart failure patients. Moreover, lymphocyte GRK2 levels are also increased in Alzheimer's disease patients and the increase was correlated with the degree of cognitive decline. By contrast, lower levels of GRK2 and GRK6 are observed in lymphocytes from rheumatoid arthritis patients. Interestingly, GRK3 and GRK5 levels appear to be increased in Parkinson's disease with dementia while GRK3 levels may be decreased in some patients with bipolar disorder or with an immune deficiency disease called 'warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome'. Collectively, these findings support the notion that hormonal signals can directly regulate GRK expression, altered GRK activity may contribute to the disease state, and lymphocyte GRK2 levels may be diagnostic in cardiovascular and neurological disease.

Several studies have also shown that GRK expression is selectively regulated as a function of the hypertensive state. In a comparison of normotensive and mildly hypertensive subjects, GRK2 protein expression in lymphocytes was positively correlated with blood pressure and negatively correlated with β_2 AR-mediated adenylyl cyclase activity. These results suggest that GRK2 expression may underlie reduced β_2 AR responsiveness characteristic of the hypertensive state. Another form of hypertension (human essential hypertension) is genetic and involves impairment in dopamine promoted urinary sodium excretion. Defective dopamine receptor/G-protein

coupling in the kidney proximal tubule is the cause of the impaired renal dopaminergic action in this form of hypertension. Interestingly, recent studies suggest that single nucleotide polymorphisms of an isoform of GRK4 (GRK4 γ) increase GRK activity and cause dopamine receptor/G-protein uncoupling in the renal proximal tubule. Moreover, expression of polymorphic GRK4 γ -A142V in transgenic mice produces hypertension and studies suggest a positive correlation between certain GRK4 polymorphisms and human hypertension. Taken together, these findings suggest that GRKs play a role in vascular and renal control and may represent novel therapeutic targets for the treatment of human hypertension.

The Arrestin Family

The first arrestin (termed 'visual arrestin' or 'arrestin1') was identified in the visual system as a 48-kDa protein that redistributed from the cytoplasm to the disk membrane following light activation of rod cell outer segments. Arrestin1 is a 404-amino-acid protein and binds to the light-receptor rhodopsin in a light- and phosphorylation-dependent manner resulting in suppression of G-protein signaling. Gene targeting has demonstrated a clear physiological role for arrestin1 in quenching phototransduction in mice while mutations in human arrestin1 have been identified in Oguchi's disease.

Evidence for a broader involvement of arrestins in the regulation of GPCRs was initially suggested by the finding that purified arrestin1 could impair β_2 AR/G-protein coupling in a phosphorylation-dependent manner. Subsequent studies identified a 418-amino-acid arrestin1 homolog (termed 'arrestin2' or ' β -arrestin1') that could effectively uncouple phosphorylated β_2 AR from G protein. Arrestin2 is widely expressed and has been broadly implicated in regulating GPCR desensitization. Arrestin2 knock-out mice appear normal although they are more sensitive to β -agonist stimulation suggesting an *in vivo* role in β AR desensitization.

A third mammalian arrestin, termed 'arrestin3' or ' β -arrestin2', is 409 amino acids and is ubiquitously expressed. Arrestin3 has also been implicated in regulating the desensitization of numerous GPCRs. Similarly, knockout studies in mice suggest a role for arrestin3 in μ -opioid receptor desensitization while a positive role in CXCR4-mediated chemotaxis has been suggested. Surprisingly, a double knock-out of arrestin2 and 3 results in an embryonic lethal phenotype suggesting an important developmental role for these proteins. Taken together, these results suggest that arrestin2 and 3 have partially overlapping specificities for regulating development and GPCR signaling.

A fourth mammalian arrestin, termed 'arrestin4' or 'X-arrestin', is 388 amino acids and is expressed specifically in cone cells. The function of arrestin4 has not been characterized. In addition to the mammalian arrestins, numerous lower eukaryotic arrestins have been identified including three in *Drosophila*, one in *C. elegans*, and at least one in zebrafish. It is worth noting that arrestins have not been identified in yeast or *Dictyostelium* although there does appear to be a family of arrestin-related proteins termed ' α -arrestins' that are widely expressed. Arrestins have no enzymatic activity and primarily function as scaffolding proteins to bring various receptors, endocytic proteins, and signaling molecules together (Table 2).

Table 2 Diverse functions of nonvisual arrestins

<i>Interacting protein^a</i>	<i>Arrestin subtype</i>	<i>Functional role</i>
Receptors		
IGF-1R	Arrestin2	Scaffolding Mdm2/intracellular trafficking/MAPK signaling
TGFβRIII	Arrestin3	Receptor internalization/TGFβ signaling
Frizzled	Arrestin3	Receptor internalization/Wnt signaling
Smoothed	Arrestin3	Activation of Gli transcriptional factor
Notch	Kurtz (fruit fly)	Receptor degradation
Trafficking		
β2 Adaptin	Arrestin2 and 3	Clathrin-mediated endocytosis of receptors
Clathrin	Arrestin2 and 3	Clathrin-mediated endocytosis of receptors
ARF6	Arrestin2 and 3	Receptor endocytosis
ARNO	Arrestin2 and 3	Regulating ARF6 activity
NSF	Arrestin2	Clathrin-mediated endocytosis of receptors
eNOS	Arrestin3	S-nitrosylation/receptor endocytosis
Signaling		
ERK1/2	Arrestin2 and 3	MAPK signaling/reorganization of actin cytoskeleton/arrestin phosphorylation
JNK3	Arrestin2 and 3	MAPK signaling/shuttling between nucleus and cytosol
MKP7	Arrestin3	Inhibiting JNK3 signaling
Akt	Arrestin3	Activation of GSK3
c-Raf	Arrestin2 and 3	MAPK signaling
c-Src	Arrestin2 and 3	ERK1/2 activation and signaling
NFκB	Arrestin2 and 3	Inhibition of NFκB-dependent signaling
IκBα	Arrestin2 and 3	Sequestering IκBα–NFκB complex
TRAF6	Arrestin2 and 3	Inhibition of IκBα and NFκB activity
DGK	Arrestin2 and 3	Diacylglycerol degradation/modulating receptor-stimulated signaling
PDE4D	Arrestin2 and 3	cAMP degradation/modulating receptor-stimulated signaling
PP2A	Arrestin2 and 3	Dephosphorylation of arrestin2, receptors and Akt/inactivation of Akt
Yes	Arrestin2	Gαq stimulation and glucose transport
Dishevelled	Arrestin2 and 3	Frizzled internalization/Wnt signaling
Ubiquitination		
Mdm2	Arrestin3	Nuclear shuttling/arrestin ubiquitination/receptor endocytosis
Nedd4	Arrestin3	Arrestin ubiquitination/receptor degradation
AIP4	Arrestin2	Degradation of CXCR4 receptor
USP33 and USP20	Arrestin3	Arrestin deubiquitination/receptor recycling
Deltex	Kurtz (fruit fly)	Ubiquitination and degradation of Notch
Others		
Ral-GDS	Arrestin2 and 3	Actin cytoskeletal rearrangement
RhoA	Arrestin2	RhoA activation and stress-fiber formation
Filamin A	Arrestin2	Change in cell shape and mobility
Cofilin	Arrestin2 and 3	Chemotaxis/actin cytoskeletal rearrangement
Kif3A	Arrestin3	Smoothed translocation to the primary cilium
NHE5	Arrestin2 and 3	NHE5 endocytosis
Histone acetylase P300	Arrestin2	Chromatin reorganization and increased transcription of <i>c-fos</i> and <i>p27</i>
Hck	Arrestin2	Granule exocytosis in granulocytes
c-Fgr	Arrestin2	Granule exocytosis in granulocytes
MPZ-1	ARR-1 (worm)	IGF-1R signaling and longevity
DAF-18 (PTEN)	ARR-1 (worm)	IGF-1R signaling and longevity

^aIGF-1R: insulin-like growth factor 1 receptor; MAPK: mitogen-activated protein kinase; TGFβRIII: type III transforming growth factor-β receptor; ARF6: ADP-ribosylation factor 6; ARNO: ARF nucleotide exchange factor; NSF: *N*-ethylmaleimide-sensitive fusion protein; eNOS: endothelial nitric oxide synthase; ERK: extracellular signal-regulated kinase (MAPK); JNK3: c-Jun N-terminal kinase 3; MKP7: MAPK phosphatase 7; c-Src: sarcoma Schmidt-Ruppin A-2 viral oncogene homolog; NFκB: nuclear factor kappa-light-chain-enhancer of activated B cells; IκBα: NFκB inhibitor α; TRAF6: E3 ligase tumor necrosis factor receptor-associated factor 6; DGK: diacylglycerol kinase; PDE4D: cAMP-specific phosphodiesterase 4D; PP2A: protein phosphatase 2; Mdm2: murine double mutant E3 ubiquitin ligase; Nedd4: HECT ubiquitin ligase neural precursor cell expressed, developmentally downregulated 4; AIP4: HECT ubiquitin ligase atrophin-interacting protein 4; USP: ubiquitin-specific processing protease; Ral-GDS: Ral GDP dissociation stimulator; RhoA: Ras homolog gene family A; Kif3A: kinesin family member 3A; NHE5: Na⁺/H⁺ exchanger isoform 5; Hck: hemopoietic cell kinase; c-Fgr: Gardner-Rasheed feline sarcoma viral oncogene homolog; MPZ-1: multi-PDZ domain containing protein; PTEN: phosphatase and tensin homolog.

Molecular and Structural Nature of Arrestin Interaction with GPCRs

Initial structural insight on arrestins was provided by the X-ray crystal structure of bovine arrestin1 while the crystal structures of C-terminally truncated and wild-type bovine arrestin2 and salamander arrestin4 have also been solved. In general, arrestins have an elongated shape and are almost exclusively made up of β sheets and connecting loops with the exception of one short α helix (Figure 3). Arrestins are composed of two major domains termed the 'N-domain' and 'C-domain' that are held together by a polar core of buried salt bridges. The N- and C-domains are connected by a short hinge while the C-tail is connected by a flexible linker to the C-domain and contains a short β strand that interacts with a lateral β strand of the N-domain. A primary region that has been suggested to undergo substantial conformational rearrangement after receptor binding is the C-tail of arrestin. In addition, the hinge connecting the N- and C-domains may play an important role in this conformational rearrangement since reducing the length of the hinge results in reduced activation of arrestin. This is consistent with the notion that the N- and C-domains move relative to each other in the process of arrestin's transition into an active conformation.

An important feature of arrestin interaction with GPCRs is the ability of arrestins to recognize both the activation and

phosphorylation state of the receptor. The ability to discriminate between agonist-activated and non-activated GPCRs suggests that arrestins contain domains that specifically contact regions of the receptor exposed following receptor activation. The N-domain of arrestins retain the ability to recognize the agonist-activated state of GPCRs, suggesting that the activation-recognition region of all arrestins is largely contained within the N-terminal half. This N-domain receptor binding region has been localized to β -strands 5 and 6 and adjacent loops while a secondary receptor-binding domain is present within β -strands 15 and 16 in the C-domain (Figure 3). As expected, swapping these two receptor-binding elements between arrestin1 and arrestin2 reverses their receptor specificity.

The importance of receptor phosphorylation in arrestin binding has also been extensively explored. The primary phosphorylation-recognition domain within arrestin1 is localized near the middle portion of the protein, while positively charged residues within β -strand 1 also participate in phosphate binding and may function to facilitate binding within the primary phosphorylation-recognition domain. Previous studies also identified a phosphorylation switch residue (Arg-175) that plays a critical role in sensing the phosphorylation state of the receptor. The conserved nature of this mechanism is supported by the observation that mutation of the comparable residue in arrestin2 (Arg-169) and arrestin3 (Arg-170) also results in an activated arrestin that binds GPCRs in a

Figure 3 Structure of arrestin2 with major interfaces for protein-protein interaction. Crystallographic structure of arrestin2 is depicted as a green cartoon model from the N-terminus (Thr-6) to the C-terminus (Met-399) together with largely disordered C-terminal flexible linker (green dotted line). Receptor-binding sites and phospholipid-binding sites are shown as arrows in this structure, together with adaptin- and clathrin-binding sites and polar core region (black dotted circles).

phosphorylation-independent manner. The phosphorylation switch residue plays a central role in the formation of a polar core comprised of charged residues from the amino-terminus (Asp-29 in arrestin2), N-domain (Arg-169 and Lys-170), C-domain (Asp-290 and Asp-297), and C-tail (Arg-393), thus bringing different parts of the protein together to maintain a basal conformation (Figure 3). These residues are highly conserved suggesting that this structural element is conserved in all arrestins and critical for function. Because the buried side chains of the polar core achieve neutrality by an elaborate network of electrostatic interactions, it has been suggested that disturbance of the polar core by introduction of a phosphate group from the receptor promotes structural changes that result in an active conformation of the protein. Indeed, conformational changes induced by incorporation of an R175Q mutation in arrestin1 have been detected by small-angle X-ray scattering. Similarly, conformational changes induced by activating mutations in arrestin2 (e.g., R169E) have been detected by hydrogen exchange mass spectrometry. In addition, bioluminescence resonance energy transfer has been used to detect conformational changes in arrestin2 induced by receptor binding. Taken together, these studies suggest that activation of arrestin results in significant structural changes that will play an important role in mediating the various protein interactions and cellular functions of arrestin.

Based on the culmination of biophysical and biochemical data, a model for arrestin-receptor interaction has been proposed. Initially, arrestin is thought to probe the functional state of the receptor and bind via its activation and phosphorylation-recognition domains. Only when the receptor is activated and phosphorylated can arrestin achieve a high affinity interaction where the activation and phosphorylation-recognition sites simultaneously engage the receptor. Lysine residues (Lys-14 and Lys-15 and perhaps others in arrestin1) located in the N-terminus are suggested to guide receptor-attached phosphates toward the phosphorylation-recognition domain and trigger the phosphate-sensitive residue, Arg-175, initiating arrestin activation. The highly charged phosphate groups are proposed to disrupt the buried polar core of arrestin releasing the constraints imposed by the C-tail on both the N- and C-domains. Phosphate binding to Lys-14 and Lys-15 is also proposed to disrupt intramolecular contacts between β -strand I, α -helix I, and the C-tail further destabilizing the basal conformation of arrestin. The various domains then rearrange and transform arrestin into the activated state optimizing arrestin-receptor interactions and facilitating arrestin interaction with endocytic proteins.

Role of Arrestins in Receptor Trafficking

Radioligand binding and immunocytochemical techniques have demonstrated that many GPCRs undergo internalization. Multiple studies have implicated an important role for GRKs and arrestins in GPCR internalization and have revealed that arrestin interaction with clathrin and AP-2, the two major proteins in clathrin-coated pits, plays an important role in this process (Table 2). Nonvisual arrestins interact specifically, stoichiometrically, and with high affinity with clathrin, and immunofluorescence analyses demonstrate that activated

GPCR, arrestin, and clathrin all colocalize upon agonist addition. The primary clathrin binding determinants in arrestins are localized to hydrophobic and acidic residues in the carboxyl-terminal region (Figure 3). Interestingly, these residues constitute a clathrin box motif, $L\phi X\phi D/E$ (where ϕ is a bulky hydrophobic residue and X represents any polar amino acid), which is a consensus sequence found in clathrin-binding proteins. A similar mutagenesis study on clathrin localized the arrestin binding site to the extreme N-terminus of the heavy chain of clathrin. Interestingly, recent structural analysis of an arrestin2/clathrin complex confirms the importance of the clathrin-binding box in this interaction but also identified a secondary binding region that contributes to the dynamics of arrestin/clathrin interaction. Nonvisual arrestins also directly interact with the endocytic adaptor AP-2, which normally functions to promote the assembly of clathrin lattices and targets receptors to clathrin-coated pits. The domain structure of AP-2 consists of four subunits (α , β 2, μ 2, and σ 2) where the β 2-subunit (β 2-adaptin) was shown to interact with an α -helical domain ($[DE]_nX_{1-2}FXX[FL]XXXR$) in nonvisual arrestins. Interestingly, the potential transition of the C-terminal β 2-adaptin binding region in arrestin from a β -sheet in the holo-protein to an α -helix when associated with β 2-adaptin has been suggested to function as a molecular switch to stabilize the activated conformation of arrestin.

Since nonvisual arrestins bind to clathrin and AP-2 with high affinity *in vitro* but appear to be primarily localized in the cytoplasm in cells, this raises questions as to what regulates arrestin association with clathrin-coated pits *in vivo*. Previous studies have suggested that the phosphorylation state of arrestin2 regulates clathrin-mediated endocytosis of the β 2AR. Upon receptor stimulation, arrestin is recruited to the plasma membrane where it is dephosphorylated, which appears to be required for targeting the activated receptor-arrestin signaling complex to clathrin-coated pits. As discussed above, intramolecular contacts of the β 2-adaptin binding domain in arrestin may effectively attenuate arrestin/AP-2 association until arrestin is activated. Indeed, activation of arrestin3 by mutation of Arg-170 significantly enhances arrestin3 binding to clathrin and β 2-adaptin. Similarly, addition of a phosphorylated receptor peptide to arrestin3 enhances arrestin3 binding to clathrin. Thus, arrestin binding to a phosphorylated activated GPCR may be the primary switch to promote conformational changes that unmask clathrin and AP-2 binding sites.

Arrestins mediate GPCR regulation by interacting with a diverse array of intracellular proteins; however, like other endocytic machinery such as AP-2 and AP180, arrestins also bind phosphoinositides (Figure 3). Arrestin2 and 3 contain a high-affinity phosphoinositide-binding site located in the C-domain that, when mutated, fails to support β 2AR internalization and receptor recruitment to clathrin-coated pits suggesting that phosphoinositides are important in delivering the receptor-arrestin complex to sites of endocytosis. Interestingly, the major visual arrestin in *Drosophila*, Arr2, also contains a highly electropositive patch of residues located in its C-domain that is involved in phosphoinositide binding. Alteration of this site interfered with Arr2 trafficking in photoreceptor cells effecting light adaptation. While PIP₂ and PIP₃ are the proposed physiological ligands for arrestins at the plasma

membrane, inositol hexakisphosphate (IP₆) displays a higher binding affinity for nonvisual arrestins than either PIP₂ or PIP₃. IP₆ is abundant in cells with concentrations ranging between 15 and 100 μM and has been proposed to regulate receptor endocytosis and receptor signaling. Interestingly, the ability of IP₆ to bind to two distinct sites on nonvisual arrestins appears to mediate homo- and hetero-oligomerization of arrestin2 and 3. Mutation of either IP₆-binding site disrupts oligomerization, and subcellular localization studies show that arrestin2 oligomers are primarily cytoplasmic whereas arrestin2 monomers display increased nuclear localization. This suggests that IP₆ binding to arrestin may regulate arrestin localization and function as a negative regulator of arrestin interaction with plasma membrane and nuclear-signaling proteins.

Role of Arrestins as Signaling Scaffolds

Numerous studies suggest that arrestins have roles beyond regulating GPCR desensitization and trafficking. Initial insight into this was provided by the finding that arrestin2 binds directly to c-Src (Table 2). This interaction appears to be mediated via proline-rich regions in arrestin2 interacting with the SH3 domain in Src although the catalytic domain may also contribute to binding. Interestingly, arrestin2/Src interaction may be regulated by phosphorylation since mutation of Ser-412 in arrestin2, the primary site of ERK1/2 phosphorylation, to an aspartate to mimic phosphorylation disrupts binding to c-Src. Thus, the current model proposes that arrestin2 binding to receptor promotes arrestin dephosphorylation enabling c-Src to bind and be recruited to clathrin-coated pits as part of a receptor/arrestin/Src complex. This may regulate Src-mediated phosphorylation of components (e.g., dynamin) that may, in turn, contribute to the regulation of GPCR trafficking and/or signaling. Interestingly, c-Src also appears to play a role in regulating dissociation of a GPCR/arrestin/AP-2 complex although the mechanism for this has not been delineated. Additional evidence for arrestin interaction with nonreceptor tyrosine kinases was found in neutrophils where treatment with IL-8 (which activates CXCR1) promotes interaction of arrestin2 with the tyrosine kinases Hck and c-fgr. Interestingly, an arrestin2 mutant defective in tyrosine kinase interaction blocks IL-8-promoted granule release suggesting that formation of an arrestin/Hck complex regulates exocytosis in neutrophils.

Additional studies have suggested a role for arrestins as mitogen-activated protein (MAP) kinase scaffolds (Table 2). Initial work focused on the potential involvement of arrestin2 in GPCR-mediated activation of ERK1/2 and demonstrated formation of complexes that contain receptor, arrestin2, ERK1/2, and either raf-1 or Src. Interestingly, inhibition of complex formation by expression of dominant negative arrestin2 or a truncated receptor that does not interact with arrestin2 inhibited both receptor endocytosis and activation of ERK1/2. Studies have also demonstrated that arrestin3 can directly bind to

JNK3 and ASK1, a JNK kinase kinase, suggesting a role for arrestin3 as a MAP kinase scaffold. Receptor stimulation results in JNK3 activation and triggers the colocalization of arrestin3 and active JNK3 with intracellular vesicles. Arrestin3 has also been implicated in activation of p38 MAP kinase although direct interaction of these proteins has not been established. It is interesting to note that for some GPCRs, arrestin2 and 3 may have differential roles in regulating MAP kinase signaling. For example, arrestin2 desensitizes angiotensin AT_{1A} receptor activation of ERK1/2 while arrestin3 plays a stimulatory role in ERK1/2 activation. By contrast, arrestin2 appears to stimulate CXCR4-mediated activation of ERK1/2 while arrestin3 desensitizes calcium flux. Thus, arrestins serve as scaffolds to mediate GPCR activation of multiple MAP kinase complexes.

Glossary

G protein A signal-transducing protein that binds guanosine triphosphate (GTP; active form) or guanosine diphosphate (GDP; inactive form). It occurs in monomeric and heterotrimeric forms. Heterotrimeric G proteins are comprised of α -, β -, and γ -subunits. The α -subunit binds the guanine nucleotides and interacts with effector enzymes or ion channels. Heterotrimeric G proteins are activated by receptors with seven-transmembrane-spanning domains termed G-protein-coupled receptors.

GAP A GTPase-activating protein that acts on monomeric and heterotrimeric G proteins to inactivate them. GAPs for heterotrimeric G proteins are RGSs and certain effectors.

Phosphorylation The modification of proteins by protein kinases and lipids by lipid kinases involving the addition of phosphate groups. This results in changes in the activity of the proteins or in the generation of new lipids with different functions.

Receptor A membrane protein that binds and is activated by hormones, neurotransmitters, growth hormones, and cytokines.

Regulators of G protein signaling (RGSs) are important controllers of the system by which many agonists (hormones and neurotransmitters) transmit their signals across the cell membrane to influence intracellular processes. This system involves heterotrimeric G proteins, which are activated when the agonists bind to their specific receptors, and effectors (enzymes and ion channels), which are the targets of the G proteins. Activation of the G proteins by the receptors involves the release of guanosine diphosphate (GDP) from their α -subunits and the subsequent binding of guanosine triphosphate (GTP), and the dissociation of the $\beta\gamma$ -subunits from the G proteins. The GTP-bound α -subunits and the free $\beta\gamma$ -subunits then act on their target effectors. Turning off the system requires the hydrolysis of GTP to GDP by the intrinsic GTPase of the α -subunits and this is a relatively slow process. RGSs accelerate the GTPase activity, thereby terminating the stimulation of effectors and allowing the G protein to revert to its GDP-liganded heterotrimeric state where it can activate again by agonist binding to receptor.

Discovery of Regulators of G Protein Signaling

RGSs were discovered as negative RGSs in *Saccharomyces cerevisiae* and *Caenorhabditis elegans*. In *S. cerevisiae*, a mutation termed SST2 caused the yeast to become supersensitive to mating pheromone. However, at the time the SST2 gene was identified, knowledge of signaling pathways was rudimentary and the connection to G proteins could not be made. Later, it became clear that signaling in yeast was similar to that in mammals, that is, the topology of pheromone receptors was similar to that of G-protein-coupled receptors and the yeast G_{α} -subunit shared considerable identity with mammalian $G_{i\alpha}$. Later, genetic evidence indicated a direct interaction between SST2 and G_{α} , and studies of mutations in G_{α} and SST2 led to the conclusion that SST2 acted as a GTPase-activating protein (GAP) for G_{α} .

Genetic analysis of *C. elegans* revealed a gene (*egl-10*) that encoded a protein that was similar in its C-terminal region to

SST2. Similar to what was found in *S. cerevisiae*, the function of EGL-10 (to increase the frequency of egg laying via serotonergic motor neurons) depended on the presence of a G_{α} protein (GOA-1) that was homologous to mammalian G_{α} .

Multiple homologs of SST2 and EGL-10 have been identified in higher eukaryotes, utilizing yeast two-hybrid screens, database searches for related sequences, polymerase chain reaction, and rescue of the SST2-deficient phenotype in yeast. A large family of RGS proteins (more than 30 members) that show activity to different G proteins has now been identified in mammals (Table 1). They differ significantly in size, but all have a diagnostic RGS core domain and exhibit GAP activity toward heterotrimeric G proteins.

Structure of RGS Proteins

RGS proteins have a conserved RGS domain of ~ 130 amino acids (Figure 1). This domain is capable of binding G_{α} subunits and stimulating GTP hydrolysis. In addition, certain RGSs have other domains in their N- and C-terminal regions. These may be PDZ, PTB, GGL, PH, DH, PX, and DEP domains, transmembrane spans, cysteine strings, and domains that bind the adenomatous polyposis coli (APC) protein, GSK3, β -catenin, PKA, GRK, and $G\beta\gamma$ (Figure 1, see legend for definitions). The presence of these domains illustrates that RGSs have more functions than GAP activity and are targeted to membranes by multiple mechanisms.

The RGS domain has been defined by X-ray crystallography as a complex between RGS4 and $G_{\alpha i1}$, and by nuclear magnetic resonance (NMR) analysis of a fragment of GAIP. The domain is globular and mostly helical in structure, based on a four-helix bundle and a second domain composed of the N- and C-terminal helices. Many of the most conserved residues face into the helical bundles, and others are involved in G_{α} binding. Three interhelix loops make contact with the three switch regions of G_{α} (those regions that show the greatest conformational changes when GDP is replaced by GTP), but there is no contact with bound GTP.

Mechanisms of RGS Proteins

RGS proteins interact with active (GTP-bound) G α -subunits and accelerate the hydrolysis of GTP. In the absence of RGSs and certain effectors, the rate of hydrolysis of GTP by G α -subunits is very slow and inappropriate for rapid on/off signaling. RGSs can increase the rate of GTP hydrolysis by up to 2000-fold. RGSs act by altering the conformation of the G α -GTP complex, thus causing G α to be a more efficient GTPase. The transition state intermediate involved in the hydrolysis of GTP can be mimicked by the complex G α -GDP-A1F4, and this has helped elucidate the mechanism of action of RGSs through crystallographic and other studies. As noted above, RGS proteins have a broad interface with G α -subunits that includes the three switch regions. In the case of RGS4, the major change exerted on G α_{zi1} is decreased mobility of switch II, and it has been suggested that switch II is stabilized in a catalytically active conformation. Due to the conservation of key residues in the contact site of the RGS domain, this mechanism is probably general. Other residues that have been shown by mutation to affect the GAP activity of the RGSs are probably involved in stabilizing the catalytic conformation of the G α -subunit or altering the affinity of RGS for G α . Although the usual mode of action of RGSs is to interact with G α -subunits, some of them can also interact directly with effectors. For example, RGS2 can inhibit type V adenylyl cyclase.

From their structure, RGS proteins are predicted to be soluble. However, their mechanism requires that they act at the plasma membrane. The generation of GTP-liganded G α -subunits in response to receptor activation would be expected to recruit RGSs to the membrane. However, transmembrane segments, lipid modifications, for example, palmitoylation, and domains that interact with membrane lipids may also be involved, and there is evidence that some RGSs can be recruited selectively to the plasma membrane by receptors.

Selectivity of RGS Action

In view of the large number of RGSs, some selectivity in their interactions with G α -subunits would be expected (Table 1). Since certain receptors can couple to more than one G protein, the selective modulation of one G α by an RGS protein can change the output from such receptors. However, selectivity has been hard to define *in vitro* and may involve restrictive patterns of cellular expression of the RGS and G α proteins. *In vitro* analysis of RGS selectivity has involved single-turnover GAP assays, studies of competition with substrate, and co-immunoprecipitation and co-adsorption assays. For example, GAIP displays activity toward G α_i and G α_q class α -subunits, but the closely related RGSZ1 and RGSZ2 are selective for G α_{zz} and display low activity toward G α_{zq} . RGS6 and RGS11 are selective for G α_{zo} compared with other G α_{zi} class subunits, and RGS2 prefers G α_{zq} . Surprisingly, only one RGS (sorting nexin 13) has been reported to act on G α_{zs} .

In a cellular setting, the selectivity of RGSs for certain G α -subunits is less readily defined than *in vitro* since the readouts are quite distal from the interactions. RGS2 displays selectivity for G α_{zq} in accordance with *in vitro* studies. RGS16 inhibits the activation of p38 MAP kinase by PAF more effectively than the activation of ERK2, whereas RGS1 has the opposite effects. In dorsal root ganglion cells, α 2-adrenergic activation of G α_{zi} and G α_{zo} was enhanced by antibodies against RGS4 and GAIP, whereas antibodies to other RGSs had no effect. Microinjection of the RGS proteins confirmed these results.

Concerning the receptor selectivity of RGS proteins, there have been few studies. In pancreatic acinar cells, RGS4 blocked G α_q -mediated PLC activation initiated by M $_3$ muscarinic, cholecystokinin, and bombesin receptors. However, it was more potent against the muscarinic receptors. RGS1 and RGS16 were also more selective against M $_3$ muscarinic receptors. Surprisingly, RGS2, which has activity toward G α_{zq} , did not show the same selectivity. The molecular basis for this receptor selectivity is presently unknown.

Significance of RGS Action

The primary action of RGSs is to induce rapid signal termination upon removal or inactivation of agonists in G-protein-coupled receptor systems. The knockout of RSG9 prolongs photon responses because G α_{zt} remains active. In addition, this approach has been used to show that RGS3 and RGS5 selectively suppress MAP kinase activation by M $_3$ muscarinic

and ATIA–angiotensin receptors, respectively, in vascular smooth muscle. On the other hand, transgenic mice overexpressing RGS4 in ventricular tissue develop less ventricular hypertrophy in response to pressure overload, apparently because of reduced $G_{\alpha q}$ action. It should also be noted that RGSs can inhibit effectors by mechanisms not involving their GAP activity. This may be because the RGSs compete with the effectors for binding the G_{α} -subunits or because the RGSs inhibit the effectors directly.

Although signal termination is an important component of RGS action, this is not the whole story. There are interesting kinetic aspects to RGS action, which arise from the cycle of activation/deactivation that G-protein-coupled receptor systems undergo. For example, the activating receptors can only interact with the GDP-liganded form of G_{α} . Thus, RGS activity can promote the association of G_{α} with the receptor through the generation of G_{α} -GDP, and permit G protein activation to continue.

Through their actions, RGS proteins modulate a variety of hormone- and neurotransmitter-stimulated responses in cells. These include the activity of adenylyl cyclase, the mitogen-activated protein kinase (MAP kinase) family, phospholipase C (with attendant changes in inositol trisphosphate and Ca^{2+} ions), G protein-gated inward rectifying K $^{+}$ (GIRK) channels, and cGMP phosphodiesterase in the retina (with altered phototransduction). Studies of the GIRK channels have

revealed that RGS proteins can alter the timing, amplitude, and duration of the K $^{+}$ currents. An interesting group of RGSs is the RhoGEFs. These are guanine-nucleotide-exchange factors for the small G protein Rho. The first of these was discovered in *Drosophila*, where genetic analysis indicated that a RhoGEF (DRhoGEF2) acted downstream of the concertina gene, which is the *Drosophila* homolog of $G_{\alpha 12}$. Several laboratories then showed that $G_{\alpha 12}$ acted directly on three mammalian homologs of DRhoGEF2 (p115 RhoGEF, PDZ-RhoGEF, and LARG). In particular, the N-terminal region of p115 was observed to be similar to the conserved region of RGSs, and p115 was found to associate with $G_{\alpha 12}$ and $G_{\alpha 13}$ through its RGS domain. Even more interesting were the findings that $G_{\alpha 13}$ could stimulate the GEF activity of p115 toward Rho, and that the RGS domain of p115 displayed GAP activity toward $G_{\alpha 12}$ and $G_{\alpha 13}$. There is now much evidence that p115 and related RhoGEFs mediate the activation of Rho induced by agonists whose receptors are coupled to G13. RGS16 inhibits $G_{\alpha 13}$ -mediated activation of Rho by binding directly to $G_{\alpha 13}$ and disrupting its interaction with p115. The binding does not involve the RGS domain of RGS16.

Although they do not contain the RGS domain, many effectors of G proteins act as GAPs toward G_{α} -subunits. Examples are phospholipase C, which acts on $G_{\alpha q}$, and the γ -subunit of cGMP phosphodiesterase, which acts on transducin. In the case of transducin, RGS proteins and the phosphodiesterase act synergistically to inactivate the G protein.

Regulation of RGS Proteins

RGS proteins can be regulated by various mechanisms. One is by transcriptional regulation of their cellular levels. Other mechanisms include covalent modification, cellular relocation, and interaction with regulatory proteins and lipids. The yeast RGS SST2 can be regulated at the transcriptional level by mating factor. Almost all RGSs are expressed in brain, although they are restricted to certain regions. They can be regulated by neurotransmitters through changes in their messenger RNA (mRNA) levels. In other tissues, there is transcriptional regulation involving growth factors and other peptides.

Regulation of RGSs also occurs at the posttranscriptional level. For example, phosphorylation can alter their degradation through ubiquitin-dependent proteolysis or by affecting a PEST sequence(s). For example, tumor necrosis factor- α (TNF α) can protect RGS7 from proteolysis through phosphorylation of a Ser/Thr sequence near the GGL and RGS domains. RGS activity can also be modified by phosphorylation of its G_x targets. Phosphorylation of $G_{\alpha z}$ by protein kinase C inhibits the GAP activity of RGS5. Another modification is reversible palmitoylation of either the RGS or its substrate G_x . The effects on the RGS may be positive or negative, depending on the assay used, but palmitoylation of G_x -subunits usually results in inhibition of the GAP activity of the RGS.

RGS proteins can bind to a variety of cellular proteins (Figure 1). As noted in the section on structure, they contain many different protein-binding motifs. They can also bind lipids, for example, PIP₃, Ca²⁺-calmodulin, and the APC protein. RGS12 is the only RGS that contains a PDZ domain and thus can interact with proteins that contain a PDZ-binding motif, for example, IL-8. AKAP2 binds the regulatory subunit of cAMP-dependent protein kinase (PKA). RGS6, RGS7, RGS9, and RGS11 contain a DEP domain and this is involved in membrane localization. Axin and conductin, which are scaffolding proteins, block signaling by Wnt proteins, which are involved in development. The RGS domains of these proteins bind the APC protein, whereas other domains bind β -catenin and GSK3.

Important interacting partners of the RGSs are the $\beta\gamma$ -subunits of G proteins ($G_{\beta\gamma}$). These bind to G_x cooperatively with respect to GDP and suppress receptor-independent activation of G proteins. They also anchor G_x to the plasma membrane and regulate many effector proteins, for example, adenylyl cyclase, phospholipase C, ion channels, and lipid kinases. With respect to RGS proteins, $G_{\beta\gamma}$ inhibits the GAP activity of many of these proteins. It appears that $G_{\beta\gamma}$ interacts with both the RGS and its target G_x -subunits. Several RGSs contain a GGL domain that is similar in sequence to $G_{\beta\gamma}$. It has also been shown that RGS11 binds $G_{\beta 5}$, and that the binding involves the GGL domain. Binding of $G_{\beta 5}$ to other RGSs has been demonstrated *in vivo*. In addition, RGSs can

inhibit the effects of $G_{\beta\gamma}$ -subunits on effectors by virtue of the generation of G_x -GDP which recombines with $G_{\beta\gamma}$ to reform inactive heterotrimeric G proteins. In the case of RGS3, there is another mechanism, namely its binding to $G_{\beta 1\gamma 2}$ -subunits to inhibit signaling to effectors. This effect involves two regions of RGS3 separate from the RGS domain.

RGS Proteins as Drug Targets

Due to the importance of G-protein-coupled receptors in regulating a large variety of physiological processes, the RGSs represent very attractive targets for therapeutic intervention. Alterations in their expression indicate that they regulate cardiac function, immune responses, neuronal function, behavior, vision, and embryonic development. There is also evidence that they may be involved in the diseases of retinitis pigmentosa, schizophrenia, Parkinson's disease, chronic heart failure, drug addiction, and prostate cancer. Drugs could be targeted to RGSs in several ways, and could act as agonists or inhibitors. The first approach is to target the RGS/ G_x interface, which involves certain amino acids that are essential for the contact. The second is through modulation of the proteins and lipids that act as allosteric modifiers of RGS action. This also includes covalent modifications. The third is modification of the membrane attachment of the RGSs since it is essential for them to be recruited to the plasma membrane in order to exert their effects. In all cases, determination of the amino-acid residues involved in RGS selectivity and in their interactions with allosteric regulators will be essential for the development of drugs of sufficient specificity to be therapeutically useful.

Glossary

Ataxia An inability to coordinate muscle activity during voluntary movement. It is often caused by disorders of the cerebellum.

Cardiac hypertrophy Enlargement of cardiomyocytes and thickening of the walls of the heart in response to hemodynamic stress and myocardial injury.

Primary hemostasis The formation of a primary platelet plug and involving platelets, the blood vessel wall, and von Willebrand factor. The process includes contraction of injured vessel, platelet adhesion, activation, aggregation, and secretion. Platelet secretion triggers the coagulation process and proceeds in a positive feedback loop to further stop bleeding.

Guanine-nucleotide-binding proteins (G proteins) are heterotrimeric proteins composed of α -, β -, and γ -subunits. Activated by G-protein-coupled receptors (GPCRs) in the plasma membrane, G proteins play pivotal roles in signal transduction from hormones, neurotransmitters, and drugs to cellular responses. The human genome has genes that code for 16 α -, 5 β -, and 12 γ -subunits. Based on functional and structural similarities, G proteins are grouped into four families named by the α -subunits they contain: G_s, G_i/G_o, G_q, and G₁₂/G₁₃. Members of the G_q family of G proteins are best characterized for their direct activation of phospholipase C β (PLC β) isozymes to produce the second messengers inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol (DAG). Unlike G_s or G_i/G_o families, the G_q family proteins are insensitive to cholera toxin and pertussis toxin. G_q is activated by *Pasteurella multocida* toxin. This potentially provides a tool for studying G_q signaling, especially since the toxin does not activate G₁₁. Its use is complicated by the fact that it also activates G_{12/13}, and possibly G_i. Its mechanism of activation is not clear, but may require proteolytic activity of the toxin, and its effects on G₁₄ and G₁₅ are not known.

G_q Family of G Proteins

Phosphatidylinositol metabolites are primary intracellular regulators of eukaryotic cells. Studies of hormone and neurotransmitter regulation of phosphatidylinositol turnover implicated the frequent involvement of a specific class of G proteins. The subsequent purification of pertussis toxin-insensitive G_z subunits led to the demonstration of guanine nucleotide regulation of PLC β isoforms through G_q. The G_q family of proteins includes G_{zq}, G_{z11}, G_{z14}, and G_{z15}, which are expressed from individual genes with different expression patterns. The human genes are designated GNAQ, GNA11, GNA14, and GNA15, respectively. G_{zq} and G_{z11} are the most similar (89% identical amino acids), whereas G_{z15} shares only about 56% identities with other family members (Figure 1). The human ortholog of G_{z15} was originally called G_{z16} because it diverged so greatly from its mouse counterpart (only 84% identities at the amino acid level compared to 96–99% identities between the other human and mouse members of this family). The four genes encoding these proteins may have arisen from a pair of gene duplications, since G_{zq} and G_{z14} are within 70 kb of each other

on human chromosome 9 or mouse chromosome 19, and G_{z11} and G_{z15} are within 7 kb of each other on human and mouse chromosomes 19 and 10, respectively. All four genes have similar structures and contain seven coding exons. Proteins likely related to the G_q family are found in the genome of many species throughout the animal kingdom, but their relationship to G_z subunits in other kingdoms is unclear.

G_q Is Activated by Hormones, Neurotransmitters, and Drugs through Multiple GPCRs

The G_q family of G proteins is responsible for cellular responses to a plethora of hormones, neurotransmitters, and drugs, and is involved in the corresponding physiological, pathophysiological, and pharmacological processes (Table 1). In the CNS, M₁, M₃, and M₅ muscarinic receptors, group I metabotropic glutamate receptors (mGluR₁ and mGluR₅), and serotonin 5-HT₂ receptors, all couple to G_q family of G proteins and thus activate the PLC β signal transduction pathway. Activation of this pathway in the CNS is involved in synaptic transmission and modulation, neuronal development, and long-term depression (LTD) and long-term potentiation.

In the cardiovascular system, α_1 adrenergic receptors, endothelin receptors, angiotensin receptors, and prostaglandin F receptors modulate cardiovascular function through activation of G_q with prominent effects on blood pressure and cardiac function. G_q signaling may play a particularly important role in the pathophysiology of cardiac hypertrophy and congestive heart failure, a compensation process induced by hemodynamic stress and myocardial injury and subsequent decompensation after sustained stimulation. The fundamental molecular mechanisms mediating cellular responses to pressure or wall stress within the heart and vessels have been elusive, but may involve G_q-mediated generation of DAG for the direct activation of a subset of transient receptor potential channels (TRPCs), particularly TRPC6. Evidence supports the idea that G_q-coupled receptors, particularly for angiotensin II (AT1R), act as pressure sensors in cell membranes even in the absence of their activating ligand. Support for this idea comes from the observation that angiotensin II receptor blockers such as losartan that are inverse agonists block stress-induced activation of TRPC6, while receptor blockers that are neutral antagonists do not.

Figure 1 Homology of G_{αq} to other human G_α proteins and to related proteins in other species. The phylogenetic tree diagram was generated by TreeView from human G protein α-subunit protein sequences aligned with ClustalX. The length of the bars connecting different G_α proteins is proportional to the similarity of their aligned sequences. The α_q homologs listed are based upon percent identical amino acids in the aligned sequences.

Table 1 Receptors that couple to the G_q family of G proteins and their ligands and physiological functions

Ligands	Receptors	Function
Acetylcholine carbachol	M ₁ , M ₃ , and M ₅ muscarinic	Memory and cognition, smooth muscle contraction, and salivary secretion
Adenine nucleotides	P ₂ Y purinergic	Vasodilation
Angiotensin II, losartan	AT _{1a} and AT _{1b}	Modulation of cardiovascular activities
Bradykinin	B ₂ bradykinin	Hyperalgesia and smooth muscle contraction
C _{5a} anaphylatoxin	C _{5a}	Chemoattraction
Cholecystikinin (CCK)	CCK _a and CCK _b	Gastrointestinal activities
Endothelins	ET _a and ET _b	Regulation of cardiovascular activities
Glutamate	mGluR ₁ and mGluR ₅	Modulation of neuronal activities
Gonadotrophin-releasing hormone (GnRH)	GnRH	Synthesis and release of FSH and LH
Histamines	H ₁	Inflammation and allergy
5-Hydroxytryptamine, α-methyl-5-HT	5-HT _{2a} , 5-HT _{2b} , and 5-HT _{2c}	Modulation of neuronal activities of the brain
Neurotensin	Neurotensin	Modulation of gastrointestinal and brain activities
Norepinephrine (noradrenaline), epinephrine (adrenaline), phenylephrine, prazosin	α _{1a} , α _{1b} , α _{1c} , and α _{1d} adrenergic	Modulation of cardiovascular activities
Platelet activating factor	PAF	Platelet activation and aggregation
Prostaglandin F _{2α}	Prostaglandin F (FP)	Bronchoconstriction and luteolysis
Thromboxane A ₂	TXA ₂ (TP)	Smooth muscle contraction and platelet aggregation
Tachykinins	NK ₁ , NK ₂ , and NK ₃	Smooth muscle contraction and transmission of sensory information
Thrombin	Thrombin	Platelet aggregation
Thyrotrophin-releasing hormone (TRH)	TRH	Synthesis and release of thyroidstimulating hormone
Vasopressin	V _{1a} and V _{1b}	Smooth muscle contraction, platelet activation, glycogenolysis, and ACTH release
Leukotrienes	CysLT ₁ and CysLT ₂	Bronchoconstriction and vasodilation

Thromboxane A₂ receptors, thrombin receptors, and purinergic receptors induce platelet aggregation and granule secretion through activation of the G_q/PLCβ pathway. The G_q family of G proteins is also involved in hormone secretion, inflammation, and allergy through the activation of many other receptors including those for thyrotrophin-releasing hormone, gonadotrophin-releasing hormone, leukotrienes, bradykinin, and histamine.

PLCβ Activation and Calcium Mobilization Are Downstream Responses to G_q Activation

Phospholipases (PLs) are membrane-associated proteins involved in the biosynthesis and degradation of membrane lipids. They include PL A₁, A₂, C, and D (PLA₁, PLA₂, PLC, and PLD). PLC contains three subclasses on the basis of size and amino acid sequences: PLCβ, PLCγ, and PLCδ. PLCβ

Figure 2 The G_q signal transduction pathway. Activation of many GPCRs leads to activation of G_q . $G_{\alpha q}$ activates $PLC\beta$ that subsequently cleaves PIP_2 to generate DAG and IP_3 . IP_3 binds to the IP_3 receptor (IP_3R) on the endoplasmic reticulum (ER) and induces release of calcium. DAG remains membrane bound and activates PKC. Both calcium and PKC are important signaling molecules that are involved in many cellular functions including cell growth and differentiation. $PLC\beta$ and regulators of G protein signaling (RGS) proteins can work as GAPs to facilitate the termination of G_q signaling by enhancing its GTPase activity.

isotypes ($\beta 1$ –4) are activated by GPCRs via G_q family and/or $\beta\gamma$ -subunits primarily from activation of the G_i/G_o family. Activated α -subunits of the G_q family stimulate all four isoforms of $PLC\beta$ with the potency rank order of $\beta 1 \geq \beta 3 \geq \beta 4 \gg \beta 2$ (Figure 2), but with the exception of $G_{\alpha 15}$, which preferentially stimulates $\beta 1$, $\beta 2$, and $\beta 3$. $PLC\beta$ hydrolyzes the membrane phospholipid phosphatidylinositol 4,5-bisphosphate (PIP_2) and generates two signal molecules: DAG and IP_3 . While DAG remains membrane associated, IP_3 is released into cytosol and binds to IP_3 receptors, which are ligand-gated Ca^{2+} channels, in the endoplasmic reticulum or sarcoplasmic reticulum (cardiac muscle cells). Binding of IP_3 induces calcium release from intracellular stores and causes a rise in cytosolic-free calcium concentration. One result of the increase in calcium concentration is its binding to calmodulin. Calcium–calmodulin complexes bind to other proteins and change their functional activities. Isozymes of protein kinase C (PKC) translocate from cytosol to plasma membrane and bind to DAG in the presence of calcium. Activated PKC phosphorylates other proteins and alters their functional state. PKC is known to have a wide variety of effects including receptor desensitization, activation of gene transcription, immune regulation, and regulation of cell growth.

The regulation of gene expression by cell-surface receptors often involves the stimulation of signaling pathways including one or more members of the mitogen-activated protein kinases (MAPKs). The MAPKs are a family of evolutionarily conserved serine/threonine kinases that transmit externally derived signals regulating cell growth, division, differentiation, and apoptosis. MAPKs are activated in response to stimulation of GPCRs that couple to the G_q family of G proteins such as α_{1b} adrenergic receptors or M_1 muscarinic cholinergic receptors. This process involves $PLC\beta$, intracellular Ca^{2+} , and PKC. PKC activation leads to MAPK activation through both Ras-dependent and Ras-independent mechanisms. PKC α can

apparently activate Raf-1 by direct phosphorylation. In many cases, however, $G_{q/11}$ activation causes MAPK activation that is unaffected by PKC inhibition.

G_q Uses Multiple Downstream Effector Mechanisms

In addition to its canonical stimulation of $PLC\beta$, G_q proteins appear to regulate other downstream effectors accounting, in part, for G_q actions not explained by effects on phosphatidylinositol metabolism. One important target appears to be p63RhoGEF, which is a guanine nucleotide exchange factor (GEF) for the activation of the small GTPase RhoA. Rho proteins regulate cytoskeletal-related processes such as secretion, cell migration, and smooth muscle contraction, as well as specific gene transcription events. A crystal structure of a $G_{\alpha i/q}$ chimera protein complexed with p63RhoGEF, and its RhoA target, confirms that G_q does not directly contact Rho but instead interacts with p63RhoGEF primarily through a region analogous to the effector-binding sites of other $G\alpha$ proteins in complex with their effector targets.

Another possible effector of G_q signaling is G protein-coupled receptor kinase 2 (GRK2). GRKs are protein kinases that participate in receptor desensitization, mediated in the case of GRK2 by its binding to $G\beta\gamma$. GRK2, and its related GRK3, also has a separate and distinct binding site for $G_{\alpha q}$ which, like p62RhoGEF, interacts with the effector binding site of the activated $G_{\alpha q}$ protein. This interaction may in part be a component of the desensitization process following G_q activation, but the GRK2- $G_{\alpha q}$ complex has also been shown to phosphorylate proteins such as insulin receptor substrate-1 (IRS-1) and a cytoskeletal regulator called ezrin. Thus, GRK2 and GRK3 have been proposed as possible downstream effectors for G_q , in addition to $PLC\beta$ and p63RhoGEF.

G_q in Cardiovascular Disease, Platelet Aggregation, and Cerebellum Development

The study of the functions of the G_q family of proteins has been greatly facilitated by the use of various animal models that overexpress the wild-type G_{αq} protein or that express a constitutively active form (gain of function mutations). Also useful have been animal models deficient in the protein, or those that overexpress an inhibitor (loss of function mutations). Some well-characterized functions of the G_q proteins include roles in the development of cerebellum and motor coordination, platelet aggregation, blood pressure responses, heart development and cardiac adaptation, and development of heart failure.

G_{αq} is essential for the signaling processes used by different platelet activators. It has been reported that a defect in human platelet G_q function leads to impaired platelet aggregation, secretion, and calcium mobilization, in response to a number of agonists. Platelets from G_{αq}-deficient mice are unresponsive to a variety of physiologic platelet activators. As a result, these mice have increased bleeding times, which is an *in vivo* measure of platelet function.

Mice with a null mutation in the G_{αq} gene suffer from ataxia with typical signs of motor coordination defects. In the cerebellum of newborn rodents, each Purkinje cell (PC) is innervated by multiple climbing fibers (CFs). Massive elimination of supernumerary CF-PC synapses occurs during the first three postnatal weeks, and by about postnatal day 20, most PCs are innervated by a single CF. In G_{αq}-deficient mice, 40% of adult PCs remain innervated by multiple CF because of a defect in regression of supernumerary CFs. PLCβ₄, which shows predominant expression in cerebellar PCs, and mGluR₁ may be involved in this function of G_{αq} since in mGluR₁- or PLCβ₄-deficient mice, a similar phenotype was observed. LTD of the PF-PC synapse in mice lacking G_{αq} was also deficient. Cerebellar LTD is a form of synaptic plasticity believed to be related to motor learning.

The G_q family of G proteins has been implicated in signaling pathways regulating cardiac growth under physiological and pathological conditions. The ability of cardiomyocytes to undergo hypertrophic growth is an important adaptive response to a wide range of conditions that require the heart to work more effectively. Norepinephrine (noradrenaline) (NE) and other hormones or regulators such as endothelin, prostaglandin F_{2α}, and angiotensin II induce cardiomyocyte growth through activation of G_q-coupled receptors. A relatively modest degree of wild-type G_{αq} overexpression in transgenic mice produced many of the features of compensated left ventricular hypertrophy. Conversely, expression of a G_{αq} inhibitor peptide that prevents receptor coupling to G_{αq} in mouse myocardium, or RGS4, which binds to and activates the GTPase activity of G_{αq}, significantly attenuated hypertrophy induced by pressure overload. The ability of cardiomyocytes to function at high capacity under increased workload usually cannot be sustained and ventricular failure develops after prolonged stimulation. One event associated with this transition to heart failure is the apoptotic death of cardiomyocytes. It has been shown that sustained or excessive activation of the G_q signaling pathway results in apoptotic loss of cardiomyocytes. Expression of a constitutively activated mutant of G_{αq}, which

further increased G_q signaling, produces initial hypertrophy, which rapidly progresses to apoptotic cardiomyocyte death. Conversely, inhibition of specific components of the pathway prevents or ameliorates heart failure. Compatible with these experimental findings, clinical studies have associated polymorphisms of the GNAQ promoter region thought to increase G_{αq} expression with outcomes or incidence of heart failure.

Modulation of G_q Functions

The G_q family of G proteins undergoes palmitoylation at N-terminal cysteine residues. Mutation of cysteines 9 and 10 in G_{αq} to serine profoundly alters the behavior of the subunit. Mutant G_{αq} cannot couple a coexpressed receptor to stimulation of PLCβ. Cysteine substitution also prevented a constitutively active form of G_{αq} from stimulating PLC directly. However, a substitution of a single cysteine in G_{αq} did not alter its activity.

Long-term activation of GPCRs coupled to G_q induces downregulation of the G_{αq} subunit. For example, prolonged exposure of αT3-1 pituitary cells to a gonadotrophin-releasing hormone receptor agonist results in marked downregulation of G_{αq} and G_{α11}. Chinese hamster ovary cells stably transfected with human M₃ muscarinic acetylcholine receptors show a 40–50% reduction in G_{αq} and G_{α11} when stimulated with the cholinergic agonist carbachol. Usually, levels of mRNA encoding G_{αq} and G_{α11} were not greatly altered, suggesting a change in protein degradation.

The intrinsic GTPase activity of G_α-subunits acts as a timer to limit the duration of G protein activation. PLCβ works as a GAP (GTPase-activating protein) to increase the intrinsic GTPase activity of G_{αq}. The ability of PLCβ to act as a GAP for G_{αq} provides negative feedback, limiting PLC activity. In addition, a family of proteins known as the regulators of G protein-signaling (RGS) proteins has been identified as GAPs for G_α-subunits. RGS4 and GAIP are known to act as GAPs for the G_q family. Furthermore, these RGS proteins block activation of PLCβ by G_{αq}, which apparently results from occlusion of the effector-binding site on G_{αq}.

The portion of GRK2 that binds G_q is an RGS homology (RH) domain with the potential to act as a GAP for terminating G_q activation. However, the GAP activity of GRK2 is very low and the crystal structure of a GRK2-G_{αi/q} chimera indicates that the GRK2 RH domain binds the effector region of G_{αq} rather than the GAP region of the protein.

The most obvious physiologic role of proteins with GAP activity would be to limit the time of action of the G_q proteins. However, GAP activity is also thought to increase the selectivity of GPCRs that couple to G_q by filtering out low-efficacy responses.

G_q Family Members Have Both Unique and Functionally Complementary Roles

Mammals express four G_q class α-subunits of which two, G_{αq} and G_{α11}, are widely expressed and are primarily responsible for coupling receptors to PLCβ. In a few cases, as in platelets, or

certain brain regions, such as the cerebellum, G_{zq} is expressed alone or in great excess over G_{z11}. In contrast to these widely expressed isoforms, G_{z14} and G_{z15} are restricted to certain tissues. G_{z14} is predominantly expressed in spleen, lung, kidney, liver, pancreas, and testis, whereas G_{z15} is primarily found in hematopoietic lineages. In most tissues, G_{zq} and G_{z11} are functionally complementary to each other. Receptors activating G_q family members in mammalian systems do not discriminate between G_{zq} and G_{z11}. Similarly, there appears to be little difference between the abilities of these G proteins in regulating PLC β functions.

Functional redundancy of G_q family proteins is also demonstrated by knocking out individual genes that code for the proteins of this family. Only G_{zq}-deficient mice revealed obvious phenotypic defects, including cerebellar ataxia and deficiencies in primary hemostasis due to a defect in platelet activation. The observed phenotypes correlated with preferential or exclusive expression of G_{zq} in the affected cell types of the cerebellum and platelets. Despite the specific expression patterns of G_{z14} and G_{z15}, which may indicate tissue-specific functions for these proteins, no obvious phenotypic changes were observed in mice carrying inactivating mutations of the G_{z14} and G_{z15} genes. G_{z11}-deficient mice were also viable and fertile with no apparent behavioral or morphologic defects.

A gene dosage effect between G_{zq} and G_{z11} was observed after breeding G_{zq}-deficient mice with G_{z11}-deficient mice. Embryos lacking both genes died in uterus with heart malformations. Mice inheriting a single copy of either gene died within hours of birth with craniofacial and/or cardiac defects. Apparently, two active alleles of these genes are required for life after birth. Analyses of intercross offspring inheriting different combinations of these two mutations indicated that G_{zq} and G_{z11} have overlapping functions in embryonic cardiomyocyte proliferation and craniofacial development.

Although studies of genetically engineered mice lacking selective G_{zq} isoforms reveal specific phenotypes only for the canonical G_{zq} isoform, analysis of signaling properties of cells derived from these animals suggests unique roles for each of the different isoforms. Although the details and consequences of these differences have been hard to elucidate based upon our current understanding of G_q signaling, one study suggested that each of the different isoforms regulates transcription of both shared and unique populations of genes in vascular smooth muscle cells. Expression of constitutively active forms of G_{zq}, G_{z14}, or G_{z15} showed that 20–34% of the genes regulated by each isoform were unique to it and not shared by any of the others. Studies such as this suggest both complementary and unique roles for each G_q protein that will likely be elucidated as more information is accumulated about recently described properties and roles of the proteins.

Green Bacteria: Chlorophyll Biosynthesis, Light-Harvesting, Reaction Centers, and Electron Transport

D A Bryant, The Pennsylvania State University, University Park, PA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Chlorophototroph A bacterium that obtains its energy for growth by chlorophyll-based light energy capture and conversion.

Chlorosome The light-harvesting antenna complexes of green bacteria. They are envelope-enclosed sacs containing up to 250 000 bacteriochlorophyll *c*, *d*, or *e* molecules that self-organize into supramolecular structures.

Energy transfer The transfer of excited-state energy between two pigment molecules by nonradiative, dipole-induced dipole resonance transfer (also called Förster resonance energy transfer). In more strongly coupled pigment systems (e.g., chlorosomes), energy transfer is better described by exciton theory.

Filamentous anoxygenic phototrophs (FAPs) Formerly green nonsulfur bacteria, these bacteria are chlorophototrophic members of the phylum *Chloroflexi*. Most FAPs are photoheterotrophs or photomixotrophs, but some are able to oxidize reduced sulfur compounds or hydrogen and grow autotrophically by fixing carbon dioxide by the 3-hydroxypropionate pathway.

Fenna–Matthews–Olson protein (FMO protein) It was the first (B)Chl protein to have its structure determined by X-ray crystallography. It is a water-soluble, BChl *a*-binding protein found in members of the green sulfur bacteria and *Candidatus* Chloracidobacterium thermophilum.

Green bacteria Bacteria belonging to three phyla within the Domain *Bacteria*, which synthesize BChl *c*, *d*, or *e* and have chlorosomes as light-harvesting antennae.

Green sulfur bacteria Chlorophototrophs belonging to the order *Chlorobiales* within the phylum *Chlorobi*. These bacteria have type-1 reaction centers, chlorosomes, and FMO in their photosynthetic apparatus. These obligately photoautotrophic organisms oxidize reduced sulfur compounds, hydrogen, or ferrous iron and fix carbon dioxide by the reverse (reductive) tricarboxylic acid (TCA) cycle.

Reaction center A (B)Chl (and carotenoid) containing protein complex that performs light-activated electron transport. Absorption of a photon leads to oxidation of a special pair of (B)Chls and reduction of an electron acceptor. Secondary electron transfer events stabilize the primary charge separation by transferring the electron to additional acceptors, which are increasingly distant from the special pair.

Type-1 reaction center Reaction centers that terminate in a chain of three [4Fe–4S] acceptors and that produce a weak oxidant and a strong reductant. Type-1 reaction centers can be homodimeric (green sulfur bacteria, heliobacteria, and *Candidatus* Chloracidobacterium thermophilum) or heterodimeric (photosystem I of cyanobacteria).

Type-2 reaction center Reaction centers that terminate in a quinone acceptor, which acts as a two-electron acceptor. Type-2 reaction centers have heterodimeric cores and produce strong oxidants and weak reductants. Bacterial type-2 reaction centers are found in purple bacteria and FAPs. Photosystem II is a water-oxidizing, type-2 reaction center found in cyanobacteria, algae, and plants.

Green Bacteria: Introduction

Green bacteria are anoxygenic chlorophototrophic bacteria: they do not produce oxygen, they use light as their primary energy source for growth, and they use (bacterio)chlorophylls ((B)Chls) for light capture and conversion into chemical energy (as adenosine triphosphate (ATP) and reducing power). Green bacteria occur as members of three phyla, *Chlorobi*, *Chloroflexi*, and *Acidobacteria*, within the Domain *Bacteria*, and the members of these three taxa differ significantly in many physiological and biochemical properties. Green sulfur bacteria (GSB; *Chlorobiales*) are obligately anaerobic photolithoautotrophs, which oxidize reduced sulfur compounds, ferrous iron, or hydrogen and reduce carbon dioxide by the reverse tricarboxylic acid (TCA) cycle. Green nonsulfur bacteria are more commonly described today as filamentous anoxygenic phototrophs (FAPs; *Chloroflexales*). Although some can oxidize sulfide and/or hydrogen and fix carbon dioxide by the 3-hydroxypropionate cycle, these organisms are principally photoheterotrophs or photomixotrophs.

Candidatus Chloracidobacterium thermophilum was only discovered very recently, and this organism is currently the only described chlorophototrophic member of the phylum *Acidobacteria*. *Candidatus* C. thermophilum does not fix carbon dioxide and is an aerobic photoheterotroph, but it has a photosynthetic apparatus very similar to that of GSB.

Chlorophototrophs convert light energy into chemical energy by using specialized, multi-subunit, pigment–protein complexes known as photochemical reaction centers (RCs). Two major classes of RCs are known in nature: type-1 RCs have three [4Fe–4S] clusters as terminal electron acceptors and produce weak oxidants and strong reductants; type-2 RCs have quinones terminal electron acceptors and produce strong oxidants and weak reductants. All RCs utilize a dimer of (B)Chl molecules, the so-called special pair, to initiate light-dependent electron transfer events. All GSB and *Candidatus* C. thermophilum (as well as Heliobacteria (phylum *Firmicutes*), which are not considered here) have homodimeric type-1 RCs that bind about 20 BChl/Chl molecules (see below), while FAPs have

(f, g) Scheme showing the *syn-anti* monomer stacks of BChl *d* in the *bchQ bchR bchU* mutant of *C. tepidum* (f) and of BChl *c* in wild-type *C. tepidum* (g).

heterodimeric type-2 RCs that are similar to the type-2 RCs of purple bacteria; they bind six total pigment molecules: three (or four) BChl *a* molecules and three (or two) bacteriopheophytin (BPhe *a*) molecules.

Although some green bacteria are actually green in color, these organisms can also be brown, orange, or reddish-brown in color. Thus, the defining property of these organisms is not their color, but two related biochemical properties. All green

bacteria synthesize BChl *c*, *d*, or *e*, and these BChl molecules are used to produce chlorosomes, which are literally sacs containing self-organized BChls, as the principal light-harvesting antenna complexes. Chlorosomes are very large light-harvesting structures (up to 30–60 nm in diameter, 100–200 nm in length) (Figure 1), and each chlorosome can contain up to 250 000 BChl *c*, *d*, or *e* molecules (Figure 2). The very high cellular content of BChl allows some green bacteria to grow at extraordinarily low-light intensities – conditions under which no other type of chlorophototroph can grow. Chlorosomes are connected to the inner surface of the cytoplasmic membrane through a structure known as the ‘baseplate’, which is a paracrystalline array of the small protein, CsmA. CsmA binds a single BChl *a* molecule and one or two carotenoid molecules (Figure 3). In GSB and *Candidatus C. thermophilum*, the baseplate is in turn attached to another BChl *a*-binding protein, the Fenna–Matthews–Olson (FMO) protein (Figures 3 and 4). FMO is a water-soluble, peripheral membrane protein that serves as the point of interconnection between the chlorosomes and the type-1 RCs in the cytoplasmic membrane. In green members of the *Chloroflexales*, such as *Chloroflexus aurantiacus*, FMO does not occur; instead, a ring of membrane-intrinsic, heterodimeric BChl *a*-binding proteins surrounds the type-2 RCs. This complex, known as B808–B866, resembles the light-harvesting-I (LH-I) complexes of purple bacteria.

Bacteriochlorophyll Biosynthesis in Green Bacteria

All GSB and *Candidatus C. thermophilum* synthesize three types of Chls: BChl *a_P*, Chl *a_{PD}*, and either BChl *c*, *d*, or *e* (the subscripts indicate the esterifying alcohol: P, phytol; PD, Δ²,6-phytyadienol; F, farnesol; S, stearyl (octadecanol)). The structure of BChl *c_F*, which is actually a family of compounds with different numbers of methyl groups at the C-8² and C-12¹ positions, is shown in Figure 2. Chlorosome-producing

Figure 2 The structure of bacteriochlorophyll *c* esterified with farnesol. The protein designations at the periphery provide the names of the gene products responsible for the modifications that lead from chlorophyllide *a* to bacteriochlorophyll *c* (also see Figure 5). The asterisk indicates the C-3¹ chiral carbon. The circle indicates the absence of a methylcarboxyl group at C-13².

Chloroflexi, for example, *Chloroflexus aurantiacus*, synthesize BChl *a_P* and BChl *c* but do not synthesize Chl *a*. Figure 5 shows the biosynthetic pathway for the synthesis of these (B)Chls. The synthesis of all Chls proceeds through a series of core reactions that convert protoporphyrin IX (1; the numbers in parentheses in bold indicate the numbered compounds in Figure 5) into chlorophyllide *a* (6), the immediate precursor of Chl *a* (18) (Figure 5). The first committed step in (B)Chl biosynthesis is the ATP-dependent insertion of Mg into protoporphyrin IX to produce Mg-protoporphyrin (2), a reaction that is catalyzed by Mg-chelatase (BchHID/ChlHID). The subsequent reaction is the methylation of the C-13² carboxyl group by BchM/ChlM. The conversion of Mg-protoporphyrin IX monomethyl ester (3) into 3,8-divinyl-protochlorophyllide *a* (4) is catalyzed by two different enzymes, BchE in anaerobes and AcsF in aerobes. The former enzyme is an oxygen-sensitive member of the radical-S-adenosylmethionine (SAM) superfamily, while the latter is an oxygen-dependent di-iron oxidase. Both introduce the C-13¹ keto group and isocyclic ring while performing a six-electron oxidation of the substrate. At least three different enzymes, BciA, BciB, and a still unidentified enzyme, also reduce the C-8 vinyl group to produce protochlorophyllide *a* (8). BciA of GSB is very similar to the NADPH-dependent enzyme of plants, while BciB is similar to the enzyme found in cyanobacteria. BciB is found in many GSB, in some members of the *Chloroflexi*, and in *Candidatus C. thermophilum*. *Roseiflexus* spp., which synthesize BChl *a* and must reduce the C-8 vinyl group, lack homologs of both BciA and BciB and therefore must have a third type of 8-vinyl reductase. In all anoxygenic bacteria, the reduction of the C-17,18 double bond of protochlorophyllide *a* (5) to produce chlorophyllide *a* (6) is catalyzed by an enzyme related to nitrogenase. This enzyme is encoded by the *bchB*, *bchN*, and *bchL* genes and, like the reduction of dinitrogen, requires the hydrolysis of ATP. Chlorophyllide *a* (6), which can directly be converted into Chl *a* (18) by chlorophyll synthase (ChlG) and BchP (geranylgeranyl reductase), is the hub compound of (B)Chl biosynthesis. This intermediate can be converted into 11 of the 14 BChl and Chl derivatives currently known to occur in chlorophototrophic bacteria.

The first committed step in the synthesis of BChl *a* is the reduction of the C-7,8 double bond of the B-ring by chlorophyllide reductase to produce 3-vinyl-bacteriochlorophyllide *a* (15). Chlorophyllide reductase is closely related to protochlorophyllide reductase by gene duplication (and by extension to nitrogenase) and is encoded by the *bchX*, *bchY*, and *bchZ* genes. The remaining steps in BChl *a* synthesis are the hydration of the C-3¹ vinyl group by BchF and subsequent oxidation of the resulting hydroxyl group to a keto moiety by BchC. BchG adds the phytol side chain to the C-17 propionate group to produce BChl *a* (19).

Chlorophyllide *a* (6) is also the immediate precursor required for the synthesis of BChl *d* (12), BChl *c* (13), and BChl *e* (14). The first committed step in the synthesis of these molecules, the removal of the C-13² methylcarboxyl group to produce 3-vinyl-bacteriochlorophyllide *d* (7), requires BciC, but the mechanism of this reaction is not yet known. Two related radical-SAM methyl transferases, BchQ and BchR, add methyl groups from S-adenosyl-L-methionine to the C-8² and

Figure 3 Scheme showing the structural organization of chlorosomes, FMO protein, and the type-1 reaction centers of *C. tepidum*. Energy transfer pathways are indicated by red arrows, and electron transfer reactions are indicated by blue arrows. The quencher is mostly chlorobiumquinone and menaquinone. Ten proteins occur in the chlorosome envelope, and the paracrystalline array of CsmA is shown in the baseplate. Blue diamonds indicate BChl a_P , and green diamonds in the reaction center indicate Chl a_{PD} molecules. In *C. tepidum*, the BChl c (white diamonds with green colored halos) form *syn-anti* monomer stacks that self-organize into coaxial nanotubes. In *Candidatus C. thermophilum*, the BChl c_s molecules appear to form folded or twisted sheets (right side of the scheme). For additional details, see text.

C-12¹ positions, to produce a family of compounds differing in their degree of methylation (see Figure 2). BchR can add a single methyl group at C-12¹, and in the GSB *Chlorobaculum tepidum*, ~95% of the BChl c molecules have the resulting ethyl group at this position. BchQ can add one, two, or three methyl groups at the C-8² position, producing *n*-propyl, isobutyl, or neopentyl side chains at this position. BchQ and BchR are not found in *C. aurantiacus*, and thus this FAP can only synthesize [8-Et, 12-Me]-BChl c . However, the BchQ and BchR methyltransferases do occur in other FAPs and are also found in *Candidatus C. thermophilum*. Depending on the degree of methylation at C-8² and C-12¹, hydration of the C-3 vinyl group, to produce a chiral center at C-3¹, is catalyzed by BchF or BchV. Highly methylated BChl c molecules have predominantly *S*-chirality at this position; [8-Et, 12-Me]-BChl c has almost exclusively *R*-chirality. BChl d (9) is methylated at C-20 by BchU, producing bacteriochlorophyllide c (10). The mechanism and gene products responsible for the oxidation of the C-7 methyl group to produce the formyl side chain of bacteriochlorophyllide e (11) are currently unknown. BChl c , d , and e are produced when BchK esterifies the corresponding

bacteriochlorophyllides with alcohols such as farnesol, geranylgeraniol, hexadecanol, and octadecanol (stearol).

Assembly of BChls in Chlorosomes

BChl c , d , and e assemble into suprastructures in chlorosomes (Figures 1(a), 1(b), 1(d), and 3), which can contain up to 250 000 BChl molecules, without the participation of proteins. Cells of the model GSB, *Chlorobaculum tepidum*, contain about 200 chlorosomes per cell (Figure 1(a)) and thus can contain up to 50 million BChl c molecules per cell, which is about 20 times greater than the number of protein molecules in such cells. *C. tepidum* chlorosomes are large and rather heterogeneous in size: length 100–200 nm and diameter 30–60 nm (Figures 1(b) and 1(d)). In addition to BChl c , the chlorosomes of *C. tepidum* contain about 2500 BChl a molecules, 5000 protein molecules (all are found in the envelope, and half of which are CsmA), 20 000 carotenoids, 18 000 chlorobiumquinone and menaquinone molecules, and 20 000 lipid molecules (glycolipids, phospholipids, and wax esters). The

Figure 4 Comparison of the X-ray structure of the FMO protein from *C. tepidum* (green) to the predicted structure of the highly divergent FMO protein from *Candidatus C. thermophilum* (red). BChl *a* molecules are shown in blue. FMO from *Candidatus C. thermophilum* is predicted to differ most from that of *C. tepidum* in the regions that interact with the reaction center (amino acids 240–250) and the chlorosome baseplate protein CsmA (amino acids 200–210). For other details, see text.

chlorosome envelope is best described as an asymmetric bilayer membrane, in which glycolipids and proteins form the outer leaflet and the esterifying alcohol tails of BChls form the inner leaflet (Figure 3). The envelope is stabilized and mostly comprised of 10 different proteins, which belong to four structure motif families: CsmA/CsmE, CsmB/CsmF/CsmH, CsmC/CsmD/CsmI, and CsmJ/CsmK/CsmL. Mutational studies in *C. tepidum* showed that CsmA is the only essential envelope protein; it forms a paracrystalline array known as the ‘baseplate’ that attaches the chlorosomes to either the FMO protein or the B808–866 complexes and RCs in the cytoplasmic membrane (see below).

Cryo-electron microscopy of chlorosomes has demonstrated that not only are chlorosomes heterogeneous in size, but also the overall organization of BChl *c* molecules inside each chlorosome is unique – that is, no two chlorosomes are structurally alike. End-on views of chlorosomes showed that the BChl *c* molecules form coaxial, concentric nanotubular structures, which are sometimes interconnected by arched lamellae (Figures 1(c) and 1(e)). The surface layers formed by the BChl tetrapyrrole head groups are separated by spacings of ~2.1 nm (vertical arrows in Figures 1(c) and 1(e)), which

are established by the hydrophobic interactions of esterifying alcohols of two adjacent layers, in much the same way a lipid bilayer membrane is stabilized by hydrophobic interactions of fatty acids. Solid-state nuclear magnetic resonance (NMR) studies showed that the BChls form stacks of *syn-anti* dimers, in which the esterifying alcohol of one molecule points above and one points below the plane formed by the head groups. The *syn-anti* dimer stacks are actually arranged as shallow helices, and the 0.83-nm repeats observed in the cryo-electron micrographs (Figure 1(c), horizontal arrows) are formed from the repeats between these *syn-anti* stacks (Figure 1(f)). In wild-type *C. tepidum* chlorosomes, these stacks run parallel to the long axis of the chlorosome (Figure 1(g)), but in a highly ordered *bchQ bchR bchU* mutant, these stacks are approximately perpendicular to the long axis of the chlorosome (Figure 1(f)).

The chlorosomes of *C. aurantiacus* are much smaller than those of *C. tepidum* (140–220 nm in length, 30–60 nm in width, and 10–20 nm in height) and have also been extensively characterized. The baseplate of these chlorosomes has a distinctive paracrystalline lattice with a 3.3-nm spacing and is probably formed from CsmA dimers. However, the suprastructural organization of the BChls in chlorosomes of *C. aurantiacus* has not yet been determined. The proteins of the chlorosome envelope of *C. aurantiacus* are very different from those of *C. tepidum*, but the same four structure-motif families are present. The chlorosomes of *Candidatus C. thermophilum* are structurally distinct from those of *C. tepidum* and *C. aurantiacus*. Cryo-electron microscopy showed that 2.3-nm lamellar spacings are present, similar to other chlorosomes, but it is clear from cryo-electron microscopy that the BChls do not form concentric nanotubes. Instead, the BChls may form folded or twisted sheets. CsmA is found in the envelopes of these chlorosomes, together with several other proteins, one of which harbors a [2Fe–2S] cluster like CsmI/CsmJ/CsmX of *C. tepidum* and CsmP of *C. aurantiacus*. The other proteins share no sequence homology with chlorosome envelope proteins in *Chlorobi* or *Chloroflexi*.

The self-assembly of BChl *c*, *d*, or *e* into suprastructures causes a significant red-shift in their absorption spectrum. For BChl *c*, the absorption shifts from about 670 nm to about 750 nm. The methylation at C-8² and C-12¹ causes the bandwidth of the absorption band to increase because of inhomogeneous broadening, and these methylations also help to tune the absorption maximum. These effects increase the absorption cross section of chlorosomes and reduce the overlap with Chl *a*, which is found in plants, algae, and cyanobacteria, and which filter the light reaching these anaerobes because of their occurrence in the upper, oxic layer of stratified aquatic environments. The high density of BChl molecules in chlorosomes produces very short inter-BChl distances and leads to very strong excitonic coupling of the BChls. Excited states due to the absorption of photons are thus delocalized over many BChls and migrate very rapidly with sub-picosecond, energy-transfer times.

The type-1 RCs of GSB and *Candidatus C. thermophilum* produce strong reductants, which can potentially produce highly toxic, reactive oxygen species when cells are exposed to oxygen. Exposure to oxygen rapidly quenches energy transfer in chlorosomes, probably by oxidation of some of the numerous quinones found in the chlorosomes. Reactivation of

Figure 5 Scheme showing the biosynthetic pathway for the synthesis of BChls *a*, *c*, *d*, and *e* as well as Chl *a* from protoporphyrin IX. The compounds are numbered, and the gene products responsible for known reactions are indicated. For further details, see text.

energy transfer requires that the oxidized quenchers are reduced again, and this appears to be the role of heterotetrameric complexes of the [2Fe-2S] proteins (e.g., CsmI, CsmJ, CsmX, or CsmP) that occur in the chlorosome envelope. The chlorosomes of *Candidatus C. thermophilum* are also highly susceptible to quenching under oxidizing conditions, and these chlorosomes contain large amounts of menaquinone. Although an Fe-S protein related to CsmI/CsmJ/CsmX is present in the chlorosome envelopes of *Candidatus C. thermophilum*, the chlorosomes of this bacterium additionally include a type-2 NADH dehydrogenase, which could transfer electrons from NADH to oxidized menaquinone to reactivate energy transfer.

The FMO BChl *a*-Binding Protein and B808-866

Light energy captured by the BChls in chlorosomes is trapped BChl *a* molecules in the baseplate; these BChl *a* molecules are bound to CsmA (Figure 3) and have an absorption maximum at about 795 nm. In all GSB and *Candidatus C. thermophilum*, this energy is then transferred to the FMO protein, a water-soluble BChl *a*-binding protein encoded by the *fmoA* gene and absorbing maximally around ~800–810 nm. FMO was the first (B)Chl protein to be crystallized, and it is a trimer composed of taco-shaped monomers that are mostly composed of beta sheets (Figures 3 and 4). The BChl *a* molecules form the filling of the taco and are covered by α -helices. Relatively long-lived quantum coherence has recently been detected in the FMO protein, which may play an important role in energy transfer. For decades it was believed that the ~40-kDa apoprotein bound seven BChl *a* molecules, but recent studies of the native protein by mass spectrometry, as well as atomic-resolution X-ray structures, have strongly suggested that an eighth BChl *a* molecule is bound to the monomer (Figure 4; also see blue diamonds in Figure 3). Mass spectrometric analyses were also used to determine the orientation of the FMO trimers relative to the RCs and chlorosome baseplate. Based upon the FMO orientation and the position of the binding site for the eighth BChl *a* molecule, it is very likely that this additional BChl *a* molecule plays an important role in energy transfer from the BChl *a* associated with the chlorosome baseplate and CsmA to FMO. It has been suggested that the esterifying alcohol of this additional BChl *a* molecule might insert into the chlorosome envelope, which could stabilize the association between these two light-harvesting structures (see Figure 3). Energy transfer from the BChl *a* pool associated with FMO to that associated with RCs is also thought to be controlled by a redox mechanism, but even under reducing, anoxic conditions, energy transfer from FMO to RCs is very inefficient *in vitro*. The biochemical basis for this inefficiency is not understood. The FMO protein of *Candidatus C. thermophilum* is very similar to that of *C. tepidum* (Figure 4; *C. tepidum* FMO structure is shown in green; the modeled *Candidatus C. thermophilum* FMO is shown in red; BChl *a* molecules are in blue) and differs significantly only in the domains predicted to contact CsmA and the RC (See Figure 4).

In *C. aurantiacus*, the BChl *a*-binding B808-866 complex replaces FMO. This complex is very similar to the LH-I complexes of purple bacteria and probably forms a ring-like

structure that surrounds the type-2 RC. Excitation energy collected by the baseplate must be transferred into the B808-866 ring, which in turn delivers the energy to the P865 special pair of the RC.

RCs in Green Bacteria

The RCs of GSB are made up of four protein subunits: PscA, PscB, PscC, and PscD, and about 16 BChl *a*, four Chl *a*, two menaquinone-7, at least one carotenoid, and three [4Fe-4S] clusters. The RC core is a homodimer of PscA molecules, which are large, 82-kDa membrane-intrinsic polypeptides with 11 transmembrane α -helices. This homodimer binds most of the electron transport cofactors and all of the pigments associated with the RCs. In addition to the core homodimer, all type-1 RCs have a second, membrane-extrinsic subunit, which is protein related to bacterial ferredoxins with two [4Fe-4S] clusters that serve as the terminal electron acceptors, usually denoted F_A and F_B . Electrons from these strongly reducing Fe/S clusters ($E_0' \sim -600$ mV) are transferred to a water-soluble electron carrier protein that is usually a soluble ferredoxin (see below). The RCs of GSB additionally include two proteins, PscC and PscD, not found in the type-1 RCs of *Candidatus C. thermophilum*. PscC encodes a membrane-anchored *c*-type cytochrome, Cyt c_Z (also known as Cyt c_{551}), which is the immediate donor of electrons to the oxidized special pair $P840^+$. There are apparently two molecules of Cyt c_Z per RC complex. PscD is a nonessential, 16-kDa subunit, which is associated with the cytoplasmic surface of the RC and is not always present in highly purified RCs. This subunit may interact with PscB and may participate in the docking of soluble electron carriers to the RC. Two FMO trimers are also tightly associated with each RC complex.

Direct absorption of a photon by the special pair, or its excitation by energy transfer from chlorosomes and/or FMO, results in the formation of an excited state, denoted as $P840^*$, of the special pair of BChl *a* molecules. The formation of this excited state causes photochemical charge separation to occur within a few picoseconds, producing $P840^+ A_0^-$, which results in an absorption decrease at 840 nm due to oxidation of the special pair. Interestingly, the primary electron acceptors, A_0 , are two of the four Chl *a* molecules found in the RC. $P840$ has a weakly oxidizing midpoint potential, $E_0' = +240$ mV, and $P840^+$ is rapidly reduced by electron transfer from Cyt c_Z ($E_0' = +180$ mV), which helps to prevent charge recombination from the reduced primary acceptor, A_0^- . Although the RCs of GSB contain two molecules of menaquinone-7, the participation of one or both of these quinones in the electron transfer chain has not been conclusively demonstrated. The terminal electron acceptor for the core complex is the F_X [4Fe-4S] cluster, which is ligated by two cysteine residues contributed by each PscA polypeptide and has a midpoint potential lower than -650 mV.

The type-1 RCs of *Candidatus C. thermophilum* have recently been isolated and characterized. The genome of this organism predicted very simple RCs composed of only two polypeptides, PscA and PscB, but because of necessity to use chaotropic agents to remove chlorosomes from the cytoplasmic membranes, PscB has not yet been observed in purified RC

preparations. The PscA polypeptide (865 amino acids) is larger than the apo-proteins of most other type-1 RCs because of the insertion of ~ 165 amino acids between trans-membrane helices 6 and 7. The PscA homodimers copurify with a carotenoid-binding protein, which is related to a type-IV pilus subunit, as a 480-kDa complex. The RC core complex had absorption maxima at 812 nm and 670 nm, and high-performance liquid chromatography (HPLC) analyses suggested the presence of 12 BChl a_P molecules and eight Chl a_{PD} molecules per P840. Surprisingly, no quinones were detected in this RC preparation. Whole cells, cell membranes, and isolated RCs all showed very similar light-induced difference spectra with maximal bleaching at 840 nm. The observed difference spectrum was very similar to that for RC preparations from *C. tepidum*.

Figure 6 Arrangement of electron transport cofactors in the type-2 reaction centers of FAPs. Each BChl a and BPheo a molecule is identified. The arrows indicate the pathway for electrons from the special pair (P865) to Q_B . For additional details, see text.

All FAPs studied to date have heterodimeric type-2 RCs, which contain subunits similar in sequence to subunits PufL and PufM of bacterial RCs. A membrane-associated tetraheme cytochrome, similar to cytochrome $c-554$, is also associated with these RCs. Type-2 RCs in characterized RCs of FAPs contain three BChl a , three BPheo a , and two menaquinones (see Figure 6). The additional BPheo a molecule, indicated as Φ_B in Figure 6, is believed to be associated with the PufM on branch of cofactors that normally is not active in electron transport (The active branch of cofactors is indicated by the arrows in Figure 6). After two photons have been absorbed, Q_B would be fully reduced and would gain two protons and would dissociate from the RC and enter the quinone pool, from which it can be oxidized by alternative complex III (see below).

Electron Transport Chains in Green Bacteria

GSB are obligately photoautotrophic, and thus they must produce both ATP and strong reductants required for carbon dioxide fixation by the reverse TCA cycle. Practically, this means that they use light energy and their type-1 RCs to produce strong reductants, that is, reduced ferredoxin and NADPH by oxidizing reduced sulfur compounds. Electrons from the F_A and F_B [4Fe-4S] clusters on PscB are presumably transferred to the small, abundant bacterial ferredoxins found in GSB cells. The redox potentials for two of these ferredoxins in *C. tepidum* are highly reducing (ca. -514 and -584 mV) and can readily support the reductive carboxylation reactions required for carbon dioxide fixation. GSB also have a ferredoxin:NADP $^+$ oxidoreductase that is more closely related to thioredoxin reductase than to the enzyme of cyanobacteria algae, and plants.

Although it seems extremely likely that GSB can perform cyclic electron transport for ATP production, the mechanism by which this occurs is presently not clear. GSB strains have an incomplete type-1 NADH dehydrogenase, which lacks the diaphorase subunits (NuoE, NuoF, and NuoG) that would be required if this complex were to oxidize pyridine nucleotides. This suggests that reduced ferredoxin, or possibly an uptake hydrogenase (or both), might deliver electrons to this complex.

Figure 7 Scheme showing the electron transport complexes identified in the genome of *Candidatus C. thermophilum*. Dotted arrows indicate possible pathways of electron transport. MQ, menaquinone/menaquinol; AC III, alternative complex III.

Electrons from menaquinol would still have to be returned to the RC by some route, and how this is accomplished is still unknown. Although GSB have genes encoding Cyt *b* (PetB) and a Rieske Fe/S protein (PetC), they seemingly do not produce a menaquinol:Cyt *c* oxidoreductase. No *c*-type cytochrome similar to Cyt *c*₁ or Cyt *f* is encoded in the genomes of GSB. It is possible that PscC/Cyt *c*₂ or another small membrane-bound, *c*-type cytochrome performs a function analogous to that of Cyt *c*₁. However, complexes capable of menaquinol oxidation have proven to be difficult to isolate and characterize.

The electron transport chain of *Candidatus C. thermophilum* has not yet been characterized biochemically, but inferences from the genome sequence suggest that it has some similarities to that of GSB. This photoheterotroph must have some mechanism to produce protonmotive force by cyclic electron transport, but it must also have a respiratory electron transport chain. It is assumed that electrons are transferred from PscB to a soluble ferredoxin and from there to ferredoxin:NADPP⁺ oxidoreductase to produce NADPH (Figure 7). Either NADPH or reduced ferredoxin must return electrons to a membrane-bound complex so that proton translocation can occur for ATP synthesis. This could occur via type-I NADH dehydrogenase, which is encoded in the genome. Cytochrome oxidase is also encoded in the genome and, surprisingly, the genome includes genes for three different complexes that could oxidize menaquinol (Figure 7). Unlike GSB but similar to FAPs, *Candidatus C. thermophilum* has alternative complex III (AC III) for oxidation of menaquinol and reduction of Cyt *c*. In addition, two Cyt *b*/Rieske complexes are encoded in the genome. These complexes have tethered Cyt *c* domains that may transfer electrons to the RCs or to cytochrome oxidase. A small soluble Cyt *c*, which could also transfer electrons among these complexes, is also encoded in the genome.

FAPs are predominantly photoheterotrophs, and they use their photosynthetic apparatus to generate protonmotive force for ATP synthesis. However, unlike purple bacteria, FAPs do not have any electron transfer complex similar to the cytochrome *bc*₁ complex (ubiquinol:cytochrome *c* oxidoreductase) that is widely distributed in bacteria. Instead, *C. aurantiacus* has two distinct alternative complex III enzymes. One may be used preferentially during growth under anoxic, phototrophic conditions and the other may be used under oxic, respiratory conditions. Exactly how electrons are transferred between these complexes and cytochrome oxidase and the RCs is still not clear. Two copper-containing proteins, auracyanin-A and auracyanin-B, may play a role in these processes.

Glossary

c-Type cytochrome A class of cytochromes in which the heme cofactor is covalently attached to the protein via thioether linkages to cysteine amino acid residues.

Cytochrome A heme-containing protein that serves as an electron transfer cofactor in biological systems.

Fe-S protein An iron-sulfur protein which holds a [2Fe-2S]-, [3Fe-4S]-, or [4Fe-4S]-type cluster and functions as an electron transfer cofactor in biological systems.

Flavoproteins A flavin adenine dinucleotide (FAD)-containing protein that serves as an electron transfer cofactor in biological systems.

P840 A special pair of bacteriochlorophyll *a* in green sulfur bacterial reaction center (RC), which serves as the primary electron donor.

P870 A special pair of bacteriochlorophyll *a* in green nonsulfur bacterial RC, which serves as the primary electron donor.

Reaction center (RC) A pigment-protein complex that converts light energy into chemical energy in photosynthetic organisms.

Green photosynthetic bacteria are a class of photosynthetic organisms that carry out light-driven electron transfer that leads to long-term energy storage. A reaction center (RC), pigment-protein complex, mediates the electron transfer process. Cytochromes, proteins that contain Fe-containing heme prosthetic groups, are an essential part of the photosynthetic electron transfer system. The green photosynthetic bacteria contain a rich variety of different cytochromes. Various cytochromes act as either soluble or membrane-bound electron carriers and are involved in substrate oxidation processes, as well as proton translocation across the membrane.

Cytochromes in Green Bacteria

There are two phyla of green photosynthetic bacteria, green sulfur bacteria and green nonsulfur bacteria, and the latter group is now more correctly called filamentous anoxygenic phototrophic (FAP) bacteria. Both groups of organisms contain cytochromes, although the patterns and types of cytochromes in the two phyla are very different.

Green sulfur bacteria (chlorobiaceae) are strictly anaerobic, photosynthetic organisms whose RC complex shares common structural and functional features with the photosystem (PS) I RC complex of plants and cyanobacteria or the heliobacterial RC complex. This type-1 (also called Fe-S-type) RC complex consists of five subunits, including a homodimeric core RC (with two identical PscA subunits with a molecular mass of 65 kDa), Fenna Matthews Olson (FMO) antenna protein (41 kDa), Fe-S protein (PscB) that includes the early electron acceptors F_A and F_B (31 kDa), cytochrome *c_z* (PscC) (22 kDa), and 18-kDa protein (PscD), respectively. Cytochrome *c_z* serves as a secondary electron donor to the primary electron donor P840. The green sulfur bacteria utilize sulfur compounds as a source of reducing power and therefore also contain additional electron transfer components, primarily soluble cytochromes *c*, which are involved in the metabolic pathway of sulfur oxidation (Figure 1).

FAP bacteria are not closely related organisms to the green sulfur bacteria, with the exception of the primary shared characteristic, the chlorosome antenna complex. Many of these organisms are facultatively aerobic photosynthetic bacteria that are often found in microbial mat environments with cyanobacteria. The only member of this group that has been well studied is *Chloroflexus aurantiacus*, which is found in hot spring environments all over the world. FAP bacteria contain a type-2 (also called quinone-type) RC complex that includes bacteriopheophytins and quinones as early electron acceptors. The type-2 RC is similar to that found in purple photosynthetic bacteria and photosystem II of oxygenic photosynthetic organisms. The FAP RC consists of a heterodimeric complex of two proteins, L and M, plus a tightly bound tetra-heme *c*-type cytochrome, *c*-554. Cyt *c*-554 is a membrane-associated cytochrome of molecular mass 48 kDa, which serves as a secondary electron donor to the primary electron donor P870. FAP bacteria have not been reported to contain any soluble *c*-type cytochromes. They also do not contain a membrane-bound cytochrome *bc*₁ complex.

Types of c-Type Cytochromes in Green Sulfur Bacteria

Recent genomic analyses of green sulfur bacteria have enabled us to see the whole picture of the photosynthetic electron transport chain linked to sulfur oxidation pathways. A number of *c*-type cytochromes are supposed to be involved in their relevant reactions as electron carriers. These include soluble cytochromes *c*-554/555, flavocytochrome *c*, and SoxAX, the membrane-bound cytochrome *c_z*, and the membrane-bound cytochrome *bc*₁ complex. The gene locus encoding each protein is presented as CT#### according to the annotation listed in the genomic database of *Chlorobium tepidum* (syn. *Chlorobaculum tepidum*). The pattern described here is similar in most species of green sulfur bacteria.

Figure 1 Schematic structural model for the reaction center and associated cytochromes involved in electron transport in photosynthetic green sulfur bacteria. Details of the various cytochromes can be found in the text.

Cytochrome c_z (PscC)

This cytochrome c_z (CT1639) is a monoheme type with a molecular mass of 23 kDa and is tightly bound to the RC complex with putative amino-terminal helices that span the membrane three times. Two molecules of cytochrome c_z are present in one RC complex. Each of them donates an electron to the P840 in a reaction mode with high viscosity dependence. The carboxyl-terminal heme-containing hydrophilic moiety seems to fluctuate on the RC surface and search for an appropriate site for the reaction to proceed. The cytochrome c_z was designated in order to characterize its functional similarity to the membrane-bound cytochrome c_y in *Rhodobacter capsulatus* and mediates the electron transfer between menaquinol:cytochrome c oxidoreductase and P840 RC complex. The exact α -peak wavelength of cytochrome c_z varies from 553 nm in membranes to 552–551 nm in a solubilized RC complex, which appears to be ascribed to some structural modification of cytochrome c_z induced by different solubilization procedures and/or a species-dependent difference.

Cytochrome c -554/555

This water-soluble cytochrome c -554/555 (CT0075) has a molecular mass of 10 kDa and gives a characteristic asymmetric α -absorption peak, similar to that of algal water-soluble cytochrome c_6 that serves as an electron donor to PSI RC. Its α -peak wavelength is species dependent: it exhibits 554 nm in *Cba. tepidum* and 555 nm in *Cba. parvum*. A locus accession number of cytochrome c -554 in *Cba. tepidum* is CT0075. The cytochrome c -554/555 donates an electron directly to the membrane-bound cytochrome c_z and never shuttles between menaquinol:cytochrome c oxidoreductase and P840 RC complex as cytochrome c_2 in purple bacteria.

Flavocytochrome c

The flavocytochrome c (FccAB/SoxEF) consists of an 11-kDa cytochrome c -553 (FccA/SoxE, CT2080) that binds a single heme plus a 47-kDa flavoprotein (FccB/SoxF, CT2081) subunit and serves as a sulfide:cytochrome c reductase. The flavoprotein subunit contains a flavin adenine dinucleotide (FAD) that is covalently bound to a cysteine residue through a thioether linkage. The electron transfer is considered to proceed as follows: $S^{2-} \rightarrow$ flavocytochrome c (FAD $\rightarrow$ heme c -553) $\rightarrow$ cytochrome c -554/555 $\rightarrow$ cytochrome c_z .

SoxAX

Although a previous observation was the involvement of dimeric cytochrome c -551 in thiosulfate oxidation, it has recently been clarified that SoxAX, which is a heterodimer of distinct monoheme-type cytochromes c (CT1019/1016) with apparent molecular masses of 30 and 10 kDa, respectively, makes a ternary complex along with SoxK (CT1020, 9 kDa) and reduces cytochrome c -554/555 in the presence of SoxB (CT1021, 60 kDa) *in vitro* by oxidizing thiosulfate. A complex probably composed of SoxYZ (CT1017/1018, 13 and 9 kDa, respectively) and SoxB is assumed to be a thiosulfate:cytochrome c reductase (TCR, 80 kDa), which had been isolated in the early 1970s but not identified biochemically.

Cytochrome bc_1 Complex

The cytochrome bc_1 complex is a multisubunit membrane-bound quinol:cytochrome c oxidoreductase found in many bacteria and in mitochondria, where it is also called complex III. It consists of a b -type cytochrome, a c -type cytochrome (cytochrome c_1), a Rieske Fe–S protein, and in some cases additional subunits. It oxidizes reduced quinone (quinol)

and transfers the electrons to soluble *c*-type cytochromes, at the same time pumping protons across the membrane and creating a proton-motive force that is used to make adenosine triphosphate (ATP). The cytochrome *bc*₁ complex from green sulfur bacteria is not as well characterized as those from other organisms; no *fbcC* (*petC*) gene coding for cytochrome *c*₁ has been found either downstream or upstream of the unit housing the *fbcF* (*petA*, CT0302) and *fbcB* (*petB*, CT0303) genes coding for the Rieske Fe-S protein and cytochrome *b*, respectively (see below). An unusual aspect of it is that it uses menaquinone, which is lower in redox potential than ubiquinone, which is used in the better-characterized complexes.

Other Cytochromes in Green Sulfur Bacteria

The genome project of *Chl. tepidum* has revealed five more *c*-type cytochromes (CT0073, CT0188, CT1704, CT1734, and CT2026) whose functions are still unknown (protein length is ~130–150 amino acids). The spectroscopic data have suggested the presence of cytochrome *c*-556, which is assumed to be a counterpart of cytochrome *c*₁ in quinol:cytochrome *c* oxidoreductase. The most probable candidate for this cytochrome *c* is considered to be CT0073, whose gene is located adjacent of CT0075 encoding cytochrome *c*-554/555.

Cytochromes in FAP Bacteria

The pattern of cytochromes in FAP bacteria is strikingly different from that found in green sulfur bacteria. The only cytochrome that has been characterized in detail is the RC-associated cytochrome *c*-554.

Cytochrome *c*-554

Cytochrome *c*-554 is a membrane-bound tetraheme cytochrome in which all four of its heme groups have α -band maxima ~554 nm. This cytochrome is the secondary electron donor to the RC and bears considerable similarity to the tetraheme cytochrome that is found in many purple photosynthetic bacteria, the best characterized is the tetraheme cytochrome from *Rhodospseudomonas viridis* (recently renamed *Blastochloris viridis*). The four heme groups in *c*-554 have redox potentials of 0 to +300 mV (vs. normal hydrogen electrode (NHE)).

Other Cytochromes in FAP Bacteria

The genomes of FAP bacteria contain other open reading frames that code for *c*-type cytochromes, although most have not been characterized. There is no cytochrome *bc*₁ complex present, as indicated by both genetic and biochemical analysis.

Alternative Complex III

Instead of the cytochrome *bc*₁ complex, another complex, now named alternative complex III is present. It contains seven distinct protein subunits and has two *c*-type cytochromes. One is a monoheme cytochrome and one is a pentaheme cytochrome. This complex has menaquinol:auracyanin oxidoreductase activity. Characterization of this complex is underway.

Glossary

Chemoheterotroph An organism that requires organic compounds and a chemical source of energy.

Excitonic interaction An interaction in which the excited state is shared by more than one molecule.

Förster energy transfer Nonradiative resonance transfer.

Heliobacteria Photosynthetic bacteria that contain bacteriochlorophyll *g* (BChl *g*) and an iron–sulfur-type reaction center (RC) similar to those found in green sulfur

bacteria and photosystem I of cyanobacteria and chloroplasts.

Homolog A molecule that is identical to another molecule except for one substituent.

Photoautotroph An organism that requires light and inorganic carbon.

Proteobacteria A subgroup of Gram-negative bacteria that includes purple photosynthetic bacteria.

Chlorosomes are the main light-harvesting structure of green filamentous bacteria and green sulfur bacteria and are filled with aggregated bacteriochlorophyll (BChl) *c*, *d*, or *e*. BChl *a* is associated with a small protein in the envelope of the chlorosome, whereas the other BChls are organized in rod-like structures located in the interior of the chlorosome and contain little or no protein. Chlorosomes are appressed to the cytoplasmic side of the cytoplasmic membrane, and the main path of excitation energy transfer can be written as

BChl *c*, *d*, or *e* (chlorosome) → BChl *a* (chlorosome)
→ BChl *a* (Fenna – Matthews – Olson,
FMO or membrane proteins)
→ BChl *a* (reaction center, RC)

Chlorosomes are the characteristic light-harvesting complexes of green filamentous bacteria (green nonsulfur bacteria, Chloroflexaceae) and green sulfur bacteria (Chlorobiaceae). Chlorosomes are filled with BChl *c*, *d*, or *e* molecules in a highly aggregated state and are appressed to the cytoplasmic side of the cytoplasmic membrane. BChl *c*, *d*, and *e* form a family of chlorophylls (chlorosome chlorophyll) that contain a hydroxyethyl group at position 3 as shown in Figure 1. The main esterifying alcohol is farnesol in green sulfur bacteria and stearyl in filamentous bacteria, which contain only BChl *c*. In some green sulfur bacteria, there are at least four chemically distinct homologs of BChl *c* that differ in the degree of alkylation on the chlorin ring at positions 8 and 12 (see Figure 1 and Table 1). In addition to chlorosome chlorophyll, all chlorosomes contain a small amount of BChl *a*, the same chlorophyll found in proteobacteria (purple bacteria). BChl *a* is associated with a small protein in the envelope of the chlorosome, whereas chlorosome chlorophyll is located in the interior and is organized in rod-like structures containing little or no protein.

Phylogeny

From a phylogenetic viewpoint, green filamentous bacteria and green sulfur bacteria are two distinct groups based on

16S rRNA, RC type, and physiology. Green filamentous bacteria contain a quinone-type RC similar to that found in proteobacteria and similar to the RC of photosystem II in cyanobacteria and plant chloroplasts as well. Green sulfur bacteria contain an iron–sulfur-type RC similar to those found in heliobacteria and in photosystem I of cyanobacteria and chloroplasts. The filamentous bacteria live either as facultative photoautotrophs or as respiring chemoheterotrophs. They are found mostly in hot springs, often in mixed populations with cyanobacteria. The sulfur bacteria are obligate photoautotrophs and strict anaerobes that grow in dim light in sulfide-rich environments such as effluents of sulfur springs and the lower layers of stratified lakes and in marine habitats. In one extreme case, green sulfur bacteria have been found at a depth of 80 m in the Black Sea.

Structural Features

Size and Internal Structure

Chlorosomes are mostly made up of chlorophyll, but lipid, protein, carotenoid, and quinone are also present. Typically, the chlorosomes from filamentous bacteria (designated F-chlorosomes) are ~100 nm long, 20–40 nm wide, and 10–20 nm high. Chlorosomes from sulfur bacteria (designated S-chlorosomes) are considerably larger with lengths 70–260 nm and widths 30–100 nm. All chlorosomes consist of a core and a 2–3-nm envelope as shown in Figure 2. The core consists of rod elements made up of aggregated chlorosome chlorophyll, while the envelope is a monolayer of mostly galactolipid and some protein. Each chlorosome may contain 10–30 rod elements. The rod elements of S-chlorosomes are 10 nm in diameter, whereas those of F-chlorosomes are only 5.2–6 nm. The envelopes of both F- and S-chlorosomes contain BChl *a* associated with a specific protein, CsmA. The molar ratio of chlorosome chlorophyll to BChl *a* in S-chlorosomes is ~90/1, whereas in F-chlorosomes it is ~25/1.

Proteins

In highly purified S-chlorosomes, the mass ratio of protein to chlorophyll is very low – only 0.5 compared to 6.3 for the FMO BChl *a* protein found in green sulfur bacteria. The proteins of chlorosomes are localized in the envelope. In F-chlorosomes, these proteins are called CsmA, CsmM, and CsmN. In S-chlorosomes, they are called CsmA, CsmB, CsmC, CsmD, and CsmE. The major component in both kinds of chlorosomes is CsmA with a molecular mass of 5.7 kDa in F-chlorosomes and 6.3 kDa in S-chlorosomes. This protein binds BChl *a* in both kinds of chlorosomes, and the BChl *a*–CsmA complexes are thought to be concentrated in a base-plate that is in contact with BChl *a* proteins associated with the cytoplasmic membrane. Some chlorosome proteins may be responsible for maintaining the native shape.

Figure 1 Structures of (a) BChl *a* and (b) the chlorosome chlorophylls (BChl *c*, *d*, and *e*). For BChl *a*, R = phytol (see Table 1 for details about the chlorosome chlorophylls).

Carotenoids

All chlorosomes contain carotenoids which function as light-harvesting pigments and triplet-state quenchers.

Spectral Properties

In Figure 3 the absorbance and fluorescence emission spectra of F-chlorosomes indicate the presence of a large amount of BChl *c*, a small amount of BChl *a*, and energy transfer from BChl *c* to BChl *a*. The absorbance and fluorescence peaks at 740 and 750 nm, respectively, belong to BChl *c*, whereas the peaks at 795 and 801 nm belong to BChl *a*. The circular dichroism (CD) spectrum (not shown) demonstrates a strong excitonic interaction among the BChl *c* molecules. All these properties of BChl *c* in both F- and S-chlorosomes are completely different from those of monomeric BChl *c* dissolved in polar solvents. Monomeric BChl *c* has absorption and fluorescence peaks at ~660 and 665 nm, and a CD spectrum with a very small negative peak at 660 nm. Pure BChl *c* forms aggregates in dried films or when dissolved in nonpolar solvents such as hexane and carbon tetrachloride. The spectral properties of these aggregates are similar to those of chlorosomes and suggest that in chlorosomes BChl *c* exists in an aggregated state. The absence of proteins from the aggregates *in vitro* supports the idea that BChl *c* does not require protein to form aggregates in the chlorosome.

Models of Chlorophyll Organization

Although it is not yet possible to present a definitive structure for the chlorophyll aggregates in the chlorosome, several characteristics have been established:

1. The aggregates of chlorosome chlorophyll (BChl *c*, *d*, or *e*) are the result of chlorophyll–chlorophyll interactions. The molecules are close together and oriented so as to give a strong excitonic interaction.
2. The chlorophyll molecules also exhibit long-range order with their Q_y transitions parallel to the long axis of the chlorosome.
3. The 13¹-carbonyl of each chlorophyll molecule interacts with a functional group on another chlorophyll molecule.
4. The 3¹-hydroxyethyl group is coordinated directly to a Mg atom in a second chlorophyll molecule and is H-bonded to the 13¹-carbonyl of a third chlorophyll molecule.
5. Essentially, all the Mg atoms in the chlorophyll molecules are five-coordinate.

Using computer modeling, Prokhorenko and colleagues have developed the useful model of chlorophyll organization

Table 1 Ring substituents found on chlorosome chlorophylls (see Figure 1)

Chlorophyll	R ₁	R ₂	R ₃	R ₄	R ₅
BChl <i>c</i> (F-chlorosomes)	Methyl	Methyl	Ethyl	Methyl	Stearyl (mostly)
BChl <i>c</i> (S-chlorosomes)	Methyl	Methyl	Ethyl <i>n</i> -propyl Isobutyl	Methylethyl	Farnesyl (mostly)
BChl <i>d</i> (S-chlorosomes)	H	Methyl	Ethyl <i>n</i> -propyl Isobutyl	Methylethyl	Farnesyl (mostly)
BChl <i>e</i> (S-chlorosomes)	Methyl	Formyl	Ethyl <i>n</i> -propyl Isobutyl	Ethyl	Farnesyl (mostly)

Figure 3 Absorption and fluorescence emission spectra of F-chlorosomes. Fluorescence was excited at 460 nm. Adapted from Brune DC, Gerola PD, and Olson JM (1990) Circular dichroism of green bacterial chromosomes. *Photosynthesis Research* 24: 253–263.

shown in Figure 4. The large-scale structure is a tube with a diameter of 4.6 nm (with respect to Mg atoms), corresponding to the diameter of the rod elements in F-chlorosomes. The chlorophyll macrocycles are perpendicular to the surface of the tube, and the hydrocarbon tails (not shown) are oriented toward the outside of the tube.

Energy Transfer

The overall pathway of excitation energy transfer upon irradiation of filamentous bacteria with red or far-red light can be written as follows:

The membrane proteins are labeled B806–866 in Figure 2(a). In sulfur bacteria, the FMO protein replaces the membrane proteins as shown in Figure 2(b). Energy transfer between chlorosome chlorophyll molecules takes place by a relatively fast exchange mechanism, whereas energy transfer between chlorosome chlorophyll and BChl *a* in the chlorosome takes place by a relatively slow Förster mechanism. The chlorosome light-harvesting system is an example of an energy funnel in which each successive pigment pool has progressively red-shifted absorption and fluorescence emission spectra. The descending energy levels thus provide an excitation gradient into the RC.

Energy transfer in the green sulfur bacteria is regulated by the redox potential *in vivo*. Under oxidizing conditions, the overall energy-transfer efficiency drops from ~100% to 10% or less. Redox titration of fluorescence in isolated chlorosomes gives a midpoint potential of –146 mV at pH 7.0. (This regulation is mediated by the quinone in the chlorosomes.)

Figure 4 (a) The arrangement of chlorosome chlorophylls in a stack. The dashed Z-axis connects the Mg atoms of the chlorophylls in a single stack. (b) Space view of the tubular chlorophyll aggregate obtained by molecular modeling. The farnsyl groups, pointing to the outside of the rod, are not shown. (c) Arrangement of chlorophyll molecules at the outside edge of the chlorosome. The formation of fluorescence quenchers at high redox potentials may protect the bacteria from lethal photo-oxidation reactions such as superoxide formation resulting from the reduction of ferredoxin in the presence of oxygen. These redox effects are largely missing from the green filamentous bacteria, whose RCs do not reduce ferredoxin.

Evolutionary Considerations

The presence of chlorosomes in both green filamentous bacteria and green sulfur bacteria is the only justification for lumping them together as green bacteria. Although the two types of chlorosomes (F and S) show differences in size and rod element morphology, the organization of the chlorosome chlorophylls appears to be basically similar, and the *csmA*/CsmA genes and proteins appear to be homologous. This suggests that the F- and S-chlorosomes are descended from a common ancestor coded for by an ancestral genome containing the *csmA* gene.

Gs Family of Heterotrimeric G Proteins

L S Weinstein, National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Inc.

Glossary

Albright hereditary osteodystrophy (AHO)

A congenital syndrome due to heterozygous $G_{s\alpha}$ mutations characterized by short stature, neurocognitive defects, subcutaneous ossifications, and brachydactyly.

Genomic imprinting An epigenetic phenomenon associated with differential DNA methylation of the two parental alleles of a gene leading to partial or complete silencing of one of the parental alleles.

Heterotrimeric G protein A protein complex consisting of an α -, β -, and γ -subunit, each the product of separate genes, which transduces signals from cell surface receptors to generate intracellular second messengers.

McCune–Albright syndrome A sporadic condition caused by widespread distribution of a somatic activating $G_{s\alpha}$ mutation.

Pseudohypoparathyroidism Conditions characterized by parathyroid hormone resistance in the renal proximal tubule.

Introduction

Heterotrimeric G proteins are primarily involved in signaling at the plasma membrane and other intracellular sites. G proteins are generally defined by their specific α -subunit, which binds guanine nucleotide and mediates signals from seven transmembrane receptors to downstream effectors. The Gs family of heterotrimeric G proteins include two closely related α -subunits that couple receptors to adenylyl cyclase and generation of cyclic adenosine monophosphate (cAMP): $G_{s\alpha}$ (stimulatory) encoded by the *GNAS* gene at 20q13 and $G_{olf\alpha}$ (olfactory) encoded by *GNAL* at 18p11. $G_{s\alpha}$ is ubiquitously expressed and is responsible for receptor-mediated cAMP responses in most tissues while $G_{olf\alpha}$ has a much more restricted tissue distribution, including the olfactory epithelium and several other neuroendocrine tissues. This article primarily focuses on $G_{s\alpha}$ biochemistry and genetics and summarizes the clinical disorders associated with $G_{s\alpha}$ defects.

General Organization of the *GNAS* Gene

The human and mouse $G_{s\alpha}$ genes (*GNAS* and *Gnas*, respectively) are located within syntenic regions (20q13.2–13.3 and distal chromosome 2, respectively) and have similar overall structure. Both orthologs also undergo similar patterns of genomic imprinting, an epigenetic phenomenon associated with allele-specific differences in DNA methylation, which results in partial or complete suppression of gene expression from one parental allele. *GNAS/Gnas* generates multiple gene products through the use of alternative promoters and first exons that splice onto a common exon (exon 2, [Figure 1](#)). The most downstream alternative exon (exon 1) generates transcripts encoding $G_{s\alpha}$. The $G_{s\alpha}$ coding region spans 13 exons (12 exons in mice). Two long and two short forms of $G_{s\alpha}$ protein are generated by alternative splicing of exon 3. The use of an alternative terminal exon (N1) located between $G_{s\alpha}$ exons 3 and 4 generates a neural-specific splice variant of unknown function. Although the $G_{s\alpha}$ promoter is not methylated, $G_{s\alpha}$ is imprinted in a tissue-specific manner, being expressed

primarily from the maternal allele in several tissues, including pituitary, thyroid, renal proximal tubules, and gonads, but biallelically expressed in most other tissues.

The most upstream alternative promoter (*Nesp* located ~45 kb upstream of $G_{s\alpha}$ exon 1 in mouse; [Figure 1](#)) generates transcripts that encode the neuroendocrine-specific protein of 55 kDa (NESP55), a chromogranin-like protein totally unrelated to $G_{s\alpha}$. NESP55 is only transcribed from the maternal allele as its promoter region is methylated on the paternal allele. Another alternative promoter (*Gnasxl* located ~30 kb upstream of $G_{s\alpha}$ exon 1 in mouse, [Figure 1](#)) generates transcripts encoding the $G_{s\alpha}$ isoform XLzs. The specific XLzs first exon encodes a long amino-terminal extension while the remainder of the protein is identical to $G_{s\alpha}$ and encoded by $G_{s\alpha}$ exons 2–13. A neural-specific truncated form of XLzs (XLN1, presumably nonfunctional) is generated by alternative splicing to the alternative terminal exon N1. In contrast to NESP55, XLzs is only expressed from the paternal allele as its promoter is methylated on the maternal allele. The same differentially methylated region also generates antisense transcripts (NESPAS) that are important for establishing imprinting at the NESP55 promoter.

Just upstream of the $G_{s\alpha}$ promoter is an alternative promoter and first exon (exon 1A, also referred to as exon A/B in humans; [Figure 1](#)) that is methylated on the maternal allele and that generates untranslated transcripts from the paternal allele. The exon 1A region is also a primary imprint control center that is required for tissue-specific imprinting of $G_{s\alpha}$, and loss of exon 1A imprinting (DNA methylation) is the underlying molecular mechanism for the development of pseudohypoparathyroidism type 1B (PHP1B).

$G_{s\alpha}$ Isoforms Encoded by *GNAS*

$G_{s\alpha}$

$G_{s\alpha}$ is ubiquitously expressed and is targeted to the inner leaflet of both plasma and intracellular membranes by palmitoylation at its amino terminus. Its major function is to couple seven transmembrane receptors to adenylyl cyclase and mediate

Figure 1 Organization of the *Gnas* locus. Schematic drawing of the *Gnas* maternal (top) and paternal (bottom) alleles with methylated regions shown above and splicing patterns shown below each allele. First exons for transcripts encoding NESP55 (NESP), Nespas, XL α s, and G α s (exon 1) are shown along with downstream exons 3–12 (13 exons in human *GNAS*) and the alternative neural-specific terminal exon N1 (exons 4–12 are shown as a single box). The mouse regions designated *Nesp*, *Nespas-Gnasxl*, and *Gnas* are indicated at the top. Horizontal arrows show active promoters while shaded boxes indicate inactive promoters. The dashed horizontal line at the paternal G α s promoter indicates that transcription is suppressed due to imprinting in a tissue-specific manner. For clarity, only the first exon for Nespas is shown. The figure is not drawn to scale. Reproduced from Weinstein LS, Xie T, Qasem A, Wang J, and Chen M (2010) The role of GNAS and other imprinted genes in the development of obesity. *International Journal of Obesity (London)* 34: 6–17.

receptor-stimulated cAMP generation. However there is evidence that G α s also directly activates other effectors, including cardiac Ca $^{2+}$ channels and Src tyrosine kinases and may be activated by the epidermal growth factor and basic fibroblast growth factor receptors. G α s may also play a role in membrane trafficking. cAMP, the major second messenger of G α s signaling, mediates its effects through direct binding and stimulation of protein kinase A, cAMP-regulated guanine nucleotide exchange factors (cAMP-GEFs), and ion channels. Protein kinase A is a serine/threonine kinase which phosphorylates many proteins, including enzymes involved in intermediary metabolism and transcription factors such as the cAMP response element binding protein (CREB). cAMP-GEFs are expressed at high levels in neuroendocrine cells and lead to activation of the ras family member Rap1.

Like all G α -subunits, prior to activation G α s has guanosine diphosphate (GDP) bound to its guanine nucleotide binding pocket and associates with $\beta\gamma$ dimers to form a heterotrimer. Upon interaction with an activated receptor, GDP is released and is replaced by ambient guanosine triphosphate (GTP), allowing G α s to achieve an active conformation leading to depalmitoylation, release from $\beta\gamma$ and the plasma membrane, and activation of adenylyl cyclase. Deactivation occurs via an intrinsic guanosine triphosphatase (GTPase) activity within G α s that hydrolyzes bound GTP to GDP.

G α s has two structural domains: a Ras-like GTPase domain, which includes sites for guanine nucleotide binding and effector interaction, and a helical domain which forms a lid over the guanine nucleotide binding site. Interactions between the two domains may be important to prevent constitutive guanine nucleotide release. Alternative splicing of exon 3 leads to two long and two short forms of G α s with helical domains of differing length. Although the ratio of long to short forms of G α s varies between cell types, all of these forms are biologically active with only subtle biochemical differences between them.

GTP binding alters the conformation of three regions (switch 1, 2, and 3 regions) within the GTPase domain allowing interactions between switch 2 and 3 and between switch 3 and the helical domain that are important to maintain the active conformation. Two highly conserved residues (Arg 201 and Gln 227 in the long form of G α s) are critical for the intrinsic GTPase catalytic activity, and therefore adenosine diphosphate (ADP)-ribosylation of Arg 201 by cholera toxin or mutations encoding substitutions of Arg 201 or Gln 227 lead to constitutive activation by disrupting the GTPase turn-off mechanism. The amino terminus and switch 2 regions directly interact with β -subunit within the heterotrimer, while the carboxyl terminus is important for receptor interactions.

XL α s

In XL α s, the first 47 amino acids of G α s are replaced by a large amino terminal domain with multiple repeat regions (the XL domain) encoded by the XL α s-specific first exon which targets XL α s to the plasma membrane and possibly to the Golgi. XL α s has been shown in cultured cells to be able to bind to $\beta\gamma$ and mediate receptor-stimulated cAMP production with the same efficacy and potency as G α s. XL α s knockout mice die soon after birth and the small number of mice that survive have increased metabolic rate and sympathetic nerve activity (SNA) as well as improved glucose tolerance and insulin sensitivity. However, it remains unclear whether XL α s has an important physiological function in humans, as patients with paternal *GNAS* mutations predicted to disrupt XL α s expression do not develop a specific phenotype.

Unlike G α s, XL α s is only expressed from the paternal *GNAS* allele and its expression is primarily limited in neuroendocrine tissues. In rats, XL α s is present in the melanotrophs within the pars intermedia of the posterior lobe, and to a lesser extent in brain, adrenal, heart, and pancreatic islets. In mouse neonates,

XLzs was shown to be expressed in brown and white adipose tissue (BAT, WAT), adrenal medulla, intermediate lobe of the pituitary, brain (hypothalamus, locus ceruleus, and the laterodorsal tegmental, hypoglossal, trigeminal, ambiguous, medullary reticular, raphe obscurus, and facial nuclei), stomach, heart, pancreas, endochondral growth plates, and kidney. XLzs expression in mouse adipose tissue is lost during the first two weeks of postnatal development.

Large amounts of a truncated XLzs (XLN1) are produced in the central nervous system by splicing to the alternative terminal exon N1, which may potentially act as a dominant negative regulator of $G_s\alpha$ signaling. It has been reported that the first XLzs exon has an alternate more upstream translational start site producing a longer product called XXLzs, which also is a functional $G_s\alpha$ isoform. XLzs exon 1 may also use an alternate reading frame to generate an unrelated basic protein named Alex, which may bind to XLzs. One study suggested that polymorphisms within XLzs exon 1 generate alternative forms of Alex and XLzs that fail to interact.

G $_s\alpha$ Defects in Human Disease

Posttranslational Modifications

From a public health standpoint, the most significant $G_s\alpha$ defect is a posttranslational ADP-ribosylation of $G_s\alpha$ residue Arg²⁰¹ catalyzed by cholera toxin, an exotoxin released by *Vibrio cholerae* during intestinal cholera infection. As Arg²⁰¹ is critical to the intrinsic GTPase turn-off mechanism, this leads to constitutive $G_s\alpha$ activity and excess cAMP in intestinal lining cells, resulting in the severe secretory diarrhea characteristic of intestinal cholera.

Activating G $_s\alpha$ Mutations

Missense mutations leading to substitution of Arg²⁰¹, or less often Gln²²⁷, lead to constitutive activation as these residues are necessary for catalyzing the GTPase turn-off reaction and therefore $G_s\alpha$ remains in the GTP-bound active form for a very extended period relative to wild-type $G_s\alpha$. As these mutations are lethal in the germline, they are always found as somatic mutations and are never transmitted to the next generation. These residues are highly conserved among $G\alpha$ subunits, and mutation of these residues leads to constitutive activation in all G proteins.

Activating $G_s\alpha$ mutations were first identified in a subset of growth hormone-secreting (somatotroph) pituitary tumors in which basal adenylyl cyclase activity was high even in the absence of stimulating hormones, such as growth hormone-releasing hormone. This subset comprises about a third of patients with growth hormone-secreting tumors (a condition known as acromegaly). Because of its ability to form tumors, the activated $G_s\alpha$ allele has also been referred to as the *gsp* oncogene. In almost all *gsp*-bearing acromegalic tumors, the activating mutation is on the maternal allele due to the fact that $G_s\alpha$ is imprinted in the pituitary somatotroph and therefore it is normally only expressed from the maternal allele in these cells. Subsequently, similar activating $G_s\alpha$ mutations were identified in a small subset of other endocrine tumors (thyroid and other tumors) and nonendocrine tumors

(e.g., ovarian tumors and myxomas) and in premature thelarche (breast development).

Similar activating $G_s\alpha$ mutations involving Arg²⁰¹ with a more widespread tissue distribution lead to McCune–Albright syndrome (MAS). Classically MAS was defined as the triad of sexual precocity (primarily in females), café-au-lait skin lesions, and polyostotic fibrous dysplasia of bone. It is now clear that these patients may also have many other features, both endocrine (adrenal adenoma and/or hyperplasia with hypercortisolism, thyroid nodules with hyperthyroidism, pituitary tumors with acromegaly, and excess prolactin secretion) and nonendocrine (e.g., biliary liver disease, cardiomyopathy with rare occurrence of sudden death, duodenal polyps, and intramuscular myxomas).

Consistent with constitutive activation of $G_s\alpha$ /cAMP pathways, the hormonal abnormalities result from overgrowth of and hypersecretion from peripheral endocrine organs independent of their respective pituitary stimulatory hormones, which mediate their effects by stimulating $G_s\alpha$ /cAMP. In fact, the pituitary hormones (thyrotropin, adrenocorticotrophic hormone, and gonadotropins) are suppressed due to negative feedback from high levels of thyroid hormone, cortisol, and estrogens or androgens, respectively. Hyperpigmentation of café-au-lait skin lesion is due to constitutive stimulation of melanin production in melanocytes via a pathway normally stimulated by melanocyte-stimulating hormone. Fibrous dysplasia of bone is characterized by focal fibrous bone lesions originating from the central marrow cavity and primarily affecting the head and axial skeleton. These lesions arise from the effect of excess cAMP in preosteoblastic mesenchymal precursor cells to inhibit differentiation and increase proliferation.

Based on the fact that MAS patients are widespread mosaics and the distribution of the café-au-lait lesions along developmental dermatomes, it is presumed that this disorder is the result of a somatic $G_s\alpha$ mutation occurring during early post-fertilization development leading to widespread distribution of cells bearing activating $G_s\alpha$ mutations. Therefore, the specific clinical presentation of each individual case is dependent upon the original site of the mutation and how late in development the mutation occurred. In fact, patients may have only 1–2 features of the classic triad, such as patients with polyostotic or monostotic fibrous dysplasia or a single endocrinopathy.

Inactivating G $_s\alpha$ Mutations

Heterozygous inactivating $G_s\alpha$ mutations lead to Albright hereditary osteodystrophy (AHO), an autosomal dominant congenital syndrome characterized by short stature, brachydactyly (shortening and widening of bones in hands and feet including metacarpals and metatarsals), neurocognitive abnormalities, subcutaneous ossifications, and characteristic facial features. Patients who inherit the mutation from the mother or have a *de novo* mutation on the maternal allele, in addition, develop early-onset obesity as well as resistance to some, but not all, hormones that activate $G_s\alpha$ in their respective target tissues (parathyroid hormone, thyrotropin, gonadotropins, and growth hormone-releasing hormone), which leads to hypocalcemia and hyperphosphatemia, hypothyroidism, reproductive abnormalities, and growth hormone deficiency, respectively. This is also referred to as pseudohypoparathyroidism type 1A (PHP1A).

Although about half of PHP1A patients have growth hormone deficiency, the short stature (as well as the brachydactyly) is due to rapid maturation and early closure of skeletal growth plates due to loss of responsiveness of growth plate chondrocytes to the paracrine factor parathyroid hormone-like peptide (PTHrP), which normally activates $G_{s\alpha}$. Patients with $G_{s\alpha}$ mutations on the paternal allele develop AHO alone in the absence of hormone resistance or obesity, a condition also referred to as pseudopseudohypoparathyroidism (PPHP). While the ectopic ossifications are generally focal and limited to the subcutaneous layer, in rare cases, more often with paternal $G_{s\alpha}$ mutations, the ossifications coalesce to form larger plate-like structures and invade the deeper soft tissues, a condition known as progressive osseous heteroplasia (POH). Overall, the AHO features that are common to both PHP1A and PPHP patients are presumed to be the result of $G_{s\alpha}$ haploinsufficiency resulting from a mutation on one parental allele (maternal in PHP1A or paternal in PPHP).

The presence or absence of hormone resistance in PHP1A versus PPHP, respectively, relates to the fact that $G_{s\alpha}$ is imprinted in the various hormone target tissues (kidney proximal tubule, thyroid, gonads, and pituitary somatotrophs) with $G_{s\alpha}$ being expressed primarily from the maternal allele in these tissues. Therefore, mutation of the active maternal allele will lead to $G_{s\alpha}$ deficiency and hormone resistance while mutation of the relatively inactive paternal allele will have little effect on $G_{s\alpha}$ expression or hormone sensitivity.

AHO is one of a small number of monogenic obesity disorders, with the caveat that obesity only occurs when the mutation is on the maternal allele (PHP1A). Mouse models have provided important insights into the likely cause of obesity in PHP1A. As in AHO patients, mice with maternal, but not paternal, germline $G_{s\alpha}$ mutation (deletion of exon 1) develop severe obesity and, in addition, develop diabetes, insulin resistance, and hyperlipidemia. In these mice, obesity is primarily due to reduction in SNA and energy expenditure rather than increased food intake. Although $G_{s\alpha}$ plays many roles in regulating peripheral metabolism in various tissues (e.g., mediating hormone-stimulated lipolysis in adipose tissue, stimulating glucose production in liver), mouse models knocking out $G_{s\alpha}$ in liver, adipose tissue, and muscle did not produce an obese phenotype. In addition, molecular studies did not show evidence for $G_{s\alpha}$ imprinting in these tissues.

Similar to what was observed with germline $G_{s\alpha}$ mutation, maternal deletion of $G_{s\alpha}$ exon 1 limited to the central nervous system (mBrGsKO) also resulted in severe obesity, diabetes, insulin resistance, and reduced SNA and energy expenditure. Central melanocortins promote negative energy balance (reduced food intake, increased SNA and energy expenditure) via receptors (MC3R, MC4R) that activate $G_{s\alpha}$ /cAMP pathways. Homozygous MC4R mutations are the most common cause of human monogenic obesity and MC4R knockout mice have a metabolic phenotype similar to that of mBrGsKO, except that MC4R mice have increased food intake as well as reduced energy expenditure. Acute administration of an MC4R agonist to mBrGsKO mice showed that these mice have reduced stimulation of energy expenditure in response to MC4R stimulation while the ability of the agonist to reduce food intake remained intact. In addition, there was molecular evidence for $G_{s\alpha}$ imprinting in the paraventricular nucleus of the hypothalamus (PVH), a site known to express MC4R receptors and to be

important in regulation of food intake and energy expenditure. It therefore appears that maternal $G_{s\alpha}$ mutations in mice (and likely in PHP1A patients as well) lead to $G_{s\alpha}$ deficiency in one or more brain regions (PVN and probably other sites) due to site-specific imprinting, and that this leads to obesity primarily via loss of melanocortin signaling to stimulate SNA and energy expenditure. While studies in XL α s knockout mice suggest that this isoform plays a role opposite to $G_{s\alpha}$ in metabolic regulation, its role, if any, in humans is unclear as PPHP patients with paternal $G_{s\alpha}$ mutations that should also disrupt XL α s do not present with a significant metabolic phenotype.

GNAS Imprinting Defects

PHP1B is a related disorder in which patients present with renal parathyroid hormone resistance in the absence of AHO features or other evidence of hormone resistance (except for borderline thyrotropin resistance in about half of the cases). Responsiveness of the skeleton to PTH is relatively maintained and therefore some PHP1B patients may present with skeletal changes resulting from chronically elevated levels of serum PTH. This condition may be familial or sporadic.

In all cases of PHP1B, methylation of the exon 1A region on the maternal allele is absent, indicating a defect in establishment or maintenance of the methylation imprint, and therefore at this site both parental alleles have a paternal (unmethylated) epigenotype. Most cases of familial PHP1B are also associated with a maternal deletion in the linked *STX16* gene located upstream of *GNAS* with no other *GNAS* methylation defects. In these families, abnormal methylation and renal PTH resistance only occur when the *STX16* deletion is inherited maternally, while those who inherit the deletion paternally are silent carriers. A small number of familial PHP1B cases are associated with maternal deletion of the NESP55 upstream region associated with loss of maternal methylation at both the XL α s and 1A promoter regions. Sporadic cases are often associated with more global methylation changes in the *GNAS* locus with no associated mutations. There is some evidence that patients with 1A methylation defects reminiscent of PHP1B may occasionally present with some features of AHO.

The absence of 1A methylation in PHP1B suggested a model by which this region contained a negative control element for the $G_{s\alpha}$ promoter that is both methylation-sensitive and tissue-specific. We proposed that the region contains a *cis*-acting suppressor element that can bind a tissue-specific repressor protein on the paternal allele, leading to suppressed $G_{s\alpha}$ expression from the paternal allele in tissues where the repressor is expressed (e.g., renal proximal tubules, thyroid, somatotrophs, etc.), but no suppression (and therefore biallelic expression) in most other tissues where the repressor is not expressed. On the maternal allele, the repressor cannot bind due to methylation and therefore the $G_{s\alpha}$ promoter remains active in the maternal allele in all tissues. In PHP1B, loss of 1A methylation allows the repressor to now bind to both alleles in specific tissues (e.g., renal proximal tubules) leading to $G_{s\alpha}$ deficiency and PTH resistance. Support for this model came from the observation that $G_{s\alpha}$ imprinting is reversed in mice with deletion of the 1A region on the paternal allele and in fact these mice show increased PTH sensitivity due to increased $G_{s\alpha}$ expression in proximal tubules.

Table 1 Phenotypes of $G_{s\alpha}$ knockout mouse models

Tissue or cell type	Phenotype
Germline (heterozygote)	Maternal – reduced survival, obesity, glucose intolerant, insulin resistant, and reduced energy expenditure Paternal – minimal phenotype
Brain (heterozygote)	Maternal – obesity, diabetes, insulin resistant, and reduced energy expenditure/sympathetic nerve activity Paternal – none
Liver (homozygote)	Hypoglycemia Increased insulin sensitivity and secretion Reduced fat mass Pancreatic α -cell hyperplasia and hyperglucagonemia
Skeletal muscle (homozygote)	Reduced muscle mass and oxidative capacity Switch to type 2 muscle fibers Improved fatigue resistance
Adipose tissue (homozygote)	Early lethality Impaired adipogenesis (white adipose tissue) Inactive brown adipose tissue and cold intolerance Increased diet-induced thermogenesis
Pancreatic islets (homozygote)	Severely reduced β cell mass and insulin-deficient diabetes Reduced body mass
Chondrocytes (homozygote)	Growth plate defects (accelerated chondrocyte proliferation) Ectopic chondrocyte formation
Osteoblasts (homozygote)	Reduced trabecular bone formation Increased cortical bone thickness Reduced B lymphocyte production
Hematopoietic stem cells (homozygote)	Impaired homing and engraftment to bone marrow
Juxtaglomerular granule (JG) cells (homozygote)	Impaired renin synthesis and release Renal failure

Conclusion

The G_s family of G proteins includes two forms, which primarily act by activating adenylyl cyclase, the ubiquitously expressed G_s and the more limited G_{olf} , both of which are defined by their specific α -subunits encoded by distinct genes. $G_{s\alpha}$ is encoded by a complex locus *GNAS* which also encodes a

paternal-specific $G_{s\alpha}$ isoform *XL α s*. $G_{s\alpha}$ defects, including post-translational modifications, activating and inactivating mutations, and abnormal imprinting, lead to many clinical disorders resulting from excess of or loss of $G_{s\alpha}$ signaling. In addition, a number of germline and tissue-specific knockouts of $G_{s\alpha}$ and *XL α s* (Table 1) have provided other important insights into the role of these signaling molecules in development, cell biology, and physiology.

Glossary

Endoplasmic reticulum First organelle of the secretory pathway. All secreted and resident proteins of the pathway are first synthesized in this organelle.

Kinase Enzyme that transfers phosphate groups, usually from ATP, to substrates. On protein substrates, it is usually added to the hydroxyl group of serine, threonine, or tyrosine side chains.

Molecular chaperone These molecules function by preventing inappropriate interactions of other molecules. Chaperones play many cellular roles including protein

folding, protein translocation, signal transduction, and protein degradation.

Proteasome Large multisubunit protein complex that mostly degrades proteins modified by poly-ubiquitin.

Transcription factor Proteins that regulate the synthesis of messenger RNA at gene promoter elements.

Ubiquitin A highly conserved 76-amino-acid protein that functions through covalent conjugation of proteins (either a target or another ubiquitin molecule) via an isopeptide bond to lysyl side chains. Ubiquitin plays roles in protein degradation, regulation of protein activity, and protein localization.

The Stress of Unfolded Proteins

Proteins are the class of molecules that perform most cellular functions. First synthesized as chains of amino acids encoded by genes, nascent proteins must fold into their correct three-dimensional structures to be active. The folded state is labile and dependent on the thermodynamic nature of each molecule. Fully mature proteins are the product of unique amino acid sequences that specify numerous noncovalent interactions within each molecule. Abrupt changes can create unfavorable local environments that weaken such interactions or prevent their correct formation. Conditions that cause the unfolding or disrupt the proper synthesis of proteins are major forms of cellular stress. Left unchecked, the inherent toxicity of unfolded proteins or their loss of function could leave cells irreversibly damaged.

The Heat Shock Response

The first stress response to unfolded proteins was reported over 40 years ago. Examination of fruit fly salivary chromosomes revealed morphological puffs along their lengths after treatment by heat, dinitrophenol, or sodium salicylate. Termed the heat shock response (HSR), it was later shown that the puffs signified activation of genes encoding heat shock

proteins (Hsps). For virtually all organisms, exposure to 5–10 °C above the optimal growth temperature leads to a robust HSR. Within the cell, an increase of this magnitude can have many deleterious effects including increased membrane fluidity and the partial unfolding of proteins.

Inputs

The HSR can be activated by wide variety of conditions beyond temperature change. A few examples include exposure to ethanol, heavy metals, amino acid analogs, mechanical damage, and conditions of hypoxia, ischemia, and osmotic stress. As temperature increases, these conditions are believed to increase the concentration of unfolded proteins. In addition, the non-stress conditions of cells undergoing rapid proliferation or differentiation also induce the HSR. Here, the physiological need is to boost the capacity for protein synthesis.

Stress Detection and Response

The HSR relies on the activity of molecular chaperone proteins to detect stress. Chaperones bind to unfolded proteins and facilitate folding by preventing inappropriate interactions. Chaperones also bind misfolded proteins to neutralize their toxicity and promote their destruction. As stress conditions increase the concentration of unfolded proteins, the available

Figure 1 Activation of the heat shock response is a multistep mechanism. The increase of unfolded proteins stimulates the binding of cytosolic chaperones and reduces the free chaperone pool. The reduction in chaperone binding to HSF monomers promotes assembly into HSF trimers (and nuclear localization of cytosolic HSF). Initial binding of trimeric HSF to heat shock promoters is in the inert state. Transcriptional activation of the target gene requires HSF phosphorylation. In yeast, HSF is similarly regulated except that it always exists as a trimer.

pool of free chaperones diminishes. Specialized sensor proteins can detect the change and initiate a response. In the eukaryotic HSR (prokaryotes employ a different mechanism), the heat shock factor (HSF) plays both stress sensor and transcription activator for the response output. In metazoan organisms, the inert state of HSF is a monomer that is maintained through associations with the chaperones Hsp70, Hsp90, and Hsp40 (Figure 1). As the demand for chaperones increases, release from chaperone complexes permits conversion of HSF to a homotrimer (and translocation into the nucleus if found in the cytosol). This form of HSF can bind to heat shock elements of heat shock genes but does so in the inert state. Transcriptional activation requires HSF phosphorylation and a conformational change. Subsequently, a dramatic but transient rise in the synthesis of Hsps is accompanied by a reduction in overall protein synthesis.

The HSR Output

Protein repair and preservation

The most notable output of the HSR is the induction of chaperone genes. Chaperones are well adapted to resist stress. Beyond their established role in the folding of most newly synthesized proteins, direct biochemical analyses have shown that some chaperones disaggregate and refold misfolded proteins. Organisms harboring mutations in chaperone genes are less tolerant to various forms of stress. Taken together, the evidence supports the view that chaperones protect cells from

stress by maintaining the folded states of proteins and repairing those that are damaged.

Degradation of aberrant proteins

Since they can be toxic, damaged proteins that cannot be repaired must to be destroyed. Fittingly, the HSR regulates key factors of protein degradative pathways. For example, another facet of chaperone function is their requirement in the degradation of misfolded proteins. In eukaryotes, offending proteins are conjugated with ubiquitin, a highly conserved 76-amino-acid protein. Poly-ubiquitin chains serve as signals for the 26 S proteasome, which degrades the attached protein. The factors responsible for the recognition and modification of substrates belong to two large enzyme families that include the ubiquitin conjugating enzymes (E2s) and the ubiquitin ligases (E3). The role of protein degradation pathways in stress tolerance is well established. For example, yeast strains that lack two heat shock genes, *UBC4* and *UBC5* (E2s), are hypersensitive to elevated temperatures and other forms of stress. A major role of the HSR in stress tolerance is to increase the cellular capacity to rapidly degrade damaged proteins.

The environmental stress response

The development of DNA microarray technology has made analysis of whole genome expression patterns possible. The application of this technology revealed that the transcriptional

Figure 2 Activation of the unfolded protein response. The accumulation of unfolded proteins in the ER reduces the free pool of BiP and activates three distinct UPR sensor/transducers. (1) PERK dimers form following the reduction of BiP (shown in red) bound to their luminal domains. Activated PERK phosphorylates eIF2 α resulting in the temporary attenuation of general translation. (2) The reduction of BiP binding to ATF6 luminal domains stimulates their relocalization to the Golgi apparatus where the transcription factor is released by intramembrane proteolysis. Soluble ATF6 translocates to the nucleus where it activates expression of a subset of UPR target genes. (3) Ire1 is activated by BiP release and direct binding of unfolded proteins which promotes its oligomerization and trans-autophosphorylation. The activated ribonuclease domain cleaves introns of messages encoding UPR-specific transcription factors. Newly synthesized Hac1 (yeast) or XBP-1 (metazoans) activates the transcription of UPR target genes. In yeast, mechanism 3 is the only known UPR pathway. Asterisks indicate activated forms of enzymes.

output of the HSR is remarkably broad. Although the HSR has its own molecular signature, a large subset of its genes is regulated similarly among disparate environmental stress conditions. These genes, comprising the environmental stress response (ESR), represent many stress-related functions and a variety of metabolic pathways. Thus, any specific stress response can be thought of as comprising the ESR plus additional outputs tailored to their specific circumstances.

The Unfolded Protein Response

The HSR primarily monitors the state of the cytosol and nucleoplasm. For the endomembrane system of the secretory pathway, the health of proteins in the endoplasmic reticulum (ER) is monitored by the unfolded protein response (UPR). Circumstances leading to ER disequilibrium and activation of the UPR include exposure to reducing agents, incomplete protein glycosylation, glucose deprivation, excess nitrogen, calcium depletion, and proteasome dysfunction. The UPR is a signal transduction pathway that relays information on the condition of the ER lumen to regulatory networks of the nucleus and cytosol.

Stress Sensors and Transmembrane Signaling

As with the HSR, increasing unfolded proteins in the ER reduces the free pool of luminal chaperones. However, since these chaperones are physically separated from downstream regulatory mechanisms, the UPR employs strategies distinct from the HSR to monitor stress. The key sensor, found in all eukaryotes, is Ire1 (**Figure 2**). Ire1 is a transmembrane protein with three functional domains. Binding of the ER chaperone BiP to the luminal domain keeps Ire1 in the inactive monomeric state. Upon stress, the luminal region of Ire1 senses the accumulation of unfolded proteins by binding them directly, which drives its oligomerization. Oligomerization stimulates trans-autophosphorylation resulting in the activation of its RNase activity. The RNase, located on the cytosolic domain of Ire1, unconventionally splices messenger RNAs encoding UPR-specific transcription factors. In budding yeast, splicing enables *HAC1* mRNA to be translated. In metazoans, the Ire1 target is *XBP-1*. Spliced *XBP-1* directs the expression of a functional UPR transcription factor that is larger and more stable from the version synthesized from the unspliced transcript. Metazoan organisms also have additional levels of UPR regulation. A membrane-bound transcription factor, ATF6 (α and β

isoforms), is released by regulated intramembrane proteolysis upon ER stress. Soluble ATF6 then translocates into the nucleus to activate UPR target genes. A third sensor is the ER transmembrane protein PERK. Like Ire1, PERK contains a kinase that is regulated by BiP occupancy of its luminal domain. By contrast, PERK targets the translation factor eIF2 α under ER stress. Phosphorylation of eIF2 α attenuates general translation.

Outputs of the UPR

The transcriptional program of the UPR shows functional similarities to the HSR but it is customized for the secretory pathway. Cells lacking an intact UPR are hypersensitive to ER stress. Under stress, such cells fail to properly fold and modify secretory proteins, trafficking functions are shut down, and misfolded proteins accumulate unabated. Accordingly, the UPR program is complex with nearly half the regulated genes having functions throughout the secretory pathway. Similar to the HSR, the deployment of chaperone proteins preserves the integrity of existing proteins, aids the folding of new proteins, and promotes the degradation of misfolded proteins. Misfolded secretory and membrane proteins are degraded by a specialized arm of ubiquitin/proteasome pathway called ER-associated protein degradation (ERAD). The ERAD pathway serves to recognize, translocate, and ubiquitylate proteins for degradation. Studies have shown that all levels of the ERAD pathway are regulated by the UPR and this regulation plays an essential role in ER stress tolerance. In metazoans, the three ER sensors appear to act coordinately to resist stress. The activity of PERK is the first line of defense. Activation of ATF6 is similarly rapid and precedes the mobilization of XBP-1. The available data indicate that key chaperone genes are ATF6 regulated while key genes of the ERAD pathway are regulated by XBP-1. Thus, a model has emerged (Figure 2) that has PERK rapidly attenuating general translation to decrease the load of unfolded proteins in the ER. This gives the existing machinery in the ER an opportunity to begin restoring homeostasis. Those efforts

are augmented by the increased synthesis of chaperone proteins directed by ATF6. If stress persists, the ERAD pathway is upregulated by the activity of XBP-1. This serves to clear those proteins that cannot be refolded in the initial response. In cells experiencing stress that cannot be ameliorated, ER-associated apoptotic pathways are activated to sacrifice afflicted cells. The phenomena may contribute to a number of prevalent diseases, including diabetes, neurodegenerative diseases, atherosclerosis, and renal disease.

Glossary

Colony stimulating factor (CSF) CSF stimulates hematopoietic progenitor/precursor cells. The prefix denotes the hematopoietic lineage stimulated by the factor, that is, M-CSF denotes macrophage or monocyte colony-stimulating activity; G-CSF stimulates granulocyte colony formation; and GM-CSF stimulates granulocyte and macrophage/monocyte colony formation.

Cytokine An extracellular signaling peptide or protein that mediates cell–cell communication, activating a

signaling cascade after interaction with a cell-surface receptor.

Hematopoiesis The process of development of mature blood cells from stem cells or precursors cells committed to blood cell formation.

Interleukin (IL) One of a number of secreted peptides or proteins, produced by lymphocytes or monocytes, which are involved in regulation of the immune system or leukocyte interactions. The number behind IL is the designation of that particular interleukin (i.e., IL-3).

The hematopoietic system consists of multipotential hematopoietic stem and progenitor cells that express hematopoietin (cytokine) receptors. These cells selectively lose or gain growth-factor receptors, which is key in the production of mature cells of specific lineages. Hematopoietin receptors comprise a superfamily of glycoproteins with structural similarities including single transmembrane spanning domains. They are activated by the binding of specific hematopoietic growth factors or cytokines, initiating a signaling cascade that results in responses including cell commitment, stimulation of proliferation or differentiation, enhancement of survival, and/or functional activation. Conserved domains in the extracellular region include cysteine pairs and a tryptophan–serine–x–tryptophan–serine (WSXWS) motif for class I receptors (see below), which are important in ligand binding. Cytoplasmic domains are diverse but have some limited similarities in membrane proximal regions known as box 1 and box 2. Box 1 and box 2 are essential for transducing mitogenic signals, and for association with and activation by Janus family (JAK) kinases. No intrinsic kinase or enzyme motif has been identified in the cytoplasmic domains of hematopoietin-receptor superfamily members. Instead, signal transduction through these receptors is regulated by their interaction with kinases of the JAK family, other cytosolic kinases, and protein messengers. Cytokine receptor signaling for all of these factors is initiated by ligand binding to the receptor, resulting in receptor oligomerization; some receptors form homodimers while others are active as hetero-oligomers. Following receptor oligomerization, the receptor-associated JAKs are phosphorylated, typically through transphosphorylation, resulting in their activation. JAK kinases subsequently phosphorylate tyrosines on the associated receptor, which then serve as docking sites for other signal transducers including the signal transducer and activator of transcription (STAT) proteins, Src kinases, protein phosphatases, and other proteins including Shc, Grb2, and phosphatidylinositol 3-kinase (PI 3-kinase), initiating a signaling cascade. Activation of hematopoietin receptors regulates responses through both transcription-dependent

and -independent pathways. Negative regulators of hematopoietin receptor signaling include tyrosine phosphatases that dephosphorylate the receptor and/or JAKs, and proteins which are members of the suppressors of cytokine-signaling family (SOCS). Hematopoietin receptor family members share many intracellular signaling molecules. The physiological function of hematopoietin receptors is complex. Some hematopoietin receptors are expressed on very early hematopoietic progenitors resulting in multilineage stimulation; others are expressed on a restricted subset or terminally differentiated cells. Many cells express more than one receptor and respond to more than one cytokine. The precise mechanisms responsible for signaling specificity remain uncertain. The *in vivo* importance of many hematopoietic receptors has been unequivocally demonstrated through deletion or over expression of the receptor or its agonist in mice, and the use of recombinant receptor agonists in humans.

Classification

Members of the hematopoietin receptor superfamily, also referred to as the cytokine receptor superfamily, can be separated into class I and class II receptors based on structural features. Class I includes: (1) receptors consisting of a single subunit which forms homodimers including those for erythropoietin (Epo), thrombopoietin (Tpo), granulocyte colony stimulating factor (G-CSF), growth hormone, and prolactin; (2) receptors consisting of two subunits, a unique α subunit and a common β subunit including those of the IL-3, GM-CSF, and IL-5 subfamily that share β_c , and the IL-6 subfamily that share the β chain gp130; and (3) heteromeric receptors for several interleukins which share the common gamma chain (γ_c) and consist of two to three subunits, α , β , and γ . A schematic representation of class I hematopoietin receptors is presented in [Figure 1](#). Class II consists of receptors for the interferons (IFNs) and certain interleukins (IL-10, IL-22, IL-24, IL-28, and IL-29). Soluble forms of cytokine receptors are formed by limited proteolysis of membrane-bound

Figure 1 Schematic representation of class I hematopoietin receptor families. The single-chain receptor (receptors for erythropoietin, thrombopoietin, G-CSF, growth hormone, and prolactin) and multiple-chain IL-3, IL-6, and IL-2 receptor families are shown.

receptors or alternative messenger RNA (mRNA) splicing. These can form a complex with specific cytokines and act antagonistically or agonistically depending on the complex involved. A second group of receptors through which hematopoietic growth factors signal, unrelated to the hematopoietin receptor family, is called the receptor tyrosine kinase gene family. This group of receptors has intrinsic tyrosine kinase activity. Examples include c-kit, the receptor for stem cell factor, which acts synergistically in culture with many other hematopoietic growth factors, and the M-CSF receptor, which is critical for monocyte/macrophage growth. This family is not discussed here. Representative members of the hematopoietin receptor family are presented as model systems for signaling of other members.

Single Subunit Hematopoietin Receptors

Epo Receptor

Expression

Epo is the primary regulator of erythropoiesis and promotes the survival, proliferation, and differentiation of erythroid cells. Epo is synthesized primarily in the kidney, and also in the liver, and its level is regulated by the arterial oxygen tension. It mediates its effects through interaction with its receptor, Epo-R, a 66-kDa protein expressed on the surface of progenitor and precursor cells committed to the erythroid lineage. The essential function of Epo-R is demonstrated by the severe anemia and death at 11–15 days gestation following homozygous deletion of the Epo or Epo-R genes in mice. The earliest cell in the erythroid lineage, the burst-forming unit erythroid, has only low numbers of Epo-R. Epo-R expression peaks at the later erythroid progenitor (colony-forming unit

erythroid) and proerythroblast stage, followed by a decline during maturation to undetectable levels in mature erythroid cells. Epo-R is also expressed on megakaryocytes and several nonhematopoietic cells including endothelial cells, myoblasts, and neuronal cells. In these nonhematopoietic cells, the biological significance of receptor expression has not been clarified. Concerns about cardiovascular and thromboembolic events, as well as promotion of tumor growth when Epo is used in cancer patients have resulted in modified use guidelines.

Signaling pathways activated by Epo

Epo-R consists of a single subunit which forms a homodimer in the presence or absence of Epo. Other members of the hematopoietin receptor family that form homodimers are receptors for Tpo (MPL), G-CSF, growth hormone, and prolactin. These receptors transduce signals for a specific cytokine but do not cross-react with other ligands of the same family. Epo binding results in a conformational change in Epo-R, allowing two JAK2, a tyrosine kinase associated with the cytoplasmic domain of Epo-R, to come into close proximity with each other. JAK2 is activated by transphosphorylation of its active site, and subsequently phosphorylates some or all of the eight tyrosine residues in the intracellular domain of Epo-R. The essential role of JAK2 in red blood cell production has been demonstrated in knockout mice. Phosphorylation of tyrosine residues on Epo-R provides docking sites for intracellular proteins to bind to Epo-R via SH2 domains, and many of these are then also tyrosine phosphorylated. However, for both Epo-R and other hematopoietin receptors, the physiologic role of tyrosines in the cytoplasmic domain in regulation of proliferative, differentiating, and survival signals requires further definition. A representation of major signaling pathways activated

Figure 2 Pathways in erythropoietin receptor signaling. Erythropoietin binding leads to activation of associated JAK2 by autotransphosphorylation. Activated JAK2 phosphorylates tyrosines in the cytoplasmic region of Epo-R as well as associated proteins. This results in activation of STAT5, Ras/Raf/MAPK, and PI 3-kinase pathways, leading to transcription and activation of genes involved in cell cycling, differentiation, and survival.

following Epo-R stimulation is shown in **Figure 2**. One of the pathways activated by Epo is STAT5. STAT5 binds to phosphorylated Epo-R and is phosphorylated by JAK2. Phosphorylated STAT5 dissociates from Epo-R and forms dimers through SH2-phosphotyrosine interactions. These dimers then translocate to the nucleus and bind specific promoter elements to activate expression of target genes. Epo-R activation by its receptor also results in activation of Ras through several pathways. Through a number of signal adapters and transducers including Grb2, Shc, GAB1, Ras guanine nucleotide exchange factors called son of sevenless (SOS), and/or a hematopoietic-specific protein with Ras/guanosine diphosphate (GDP)/guanosine triphosphate (GTP) nucleotide exchange activity called Vav, Ras is activated by increased exchange of GDP with GTP. Epo stimulation also results in inhibition of GTPase-activating protein by Epo-induced tyrosine phosphorylation. Following Ras activation, a downstream cascade proceeds including phosphorylation and activation of Raf-1, and of mitogen-activated protein kinases (MAPKs), with subsequent induction of immediate-early genes including c-fos, c-myc, and c-jun. PI 3-kinase is another important kinase activated by Epo-R, either through direct association of the SH2 domain of the 85-kDa PI 3-kinase subunit with activated Epo-R or by binding to Epo-R through IRS-2 (insulin receptor substrate-2). PI 3-kinase can activate downstream targets including Akt, a kinase with crucial anti-apoptotic activity, and p70^{S6K}, a kinase that phosphorylates ribosomal protein S6 and plays an important role in transcription, translation, and cell-cycle progression. Ligand binding of Epo-R also results in an increase in intracellular calcium, a universal second messenger that influences many cell functions, through a mechanism involving activation of the transient receptor potential (TRP) channel TRPC3. Tyrosine phosphorylation in erythroid cells is down modulated by the hematopoietic protein tyrosine phosphatase SH-PTP1 (SHP1), which acts as a negative regulator. SH-PTP1 is recruited via its SH2 domains to tyrosine-phosphorylated Epo-R, dephosphorylates JAK2 and terminates proliferative signals.

Negative regulation is also mediated through SOCS proteins. One example is the SOCS protein CIS (cytokine-inducible SH2-containing protein), which may compete with STAT5 for binding sites on Epo-R and through this mechanism modify JAK/STAT signaling. CIS is also ubiquitinated and along with SOCS3 promotes Epo-R proteasomal degradation. A number of other nonreceptor protein kinases, phosphatases, and phospholipases have also been shown to have important roles in Epo-R signal transduction, as well as additional adapters and transducers, including phospholipase C γ , Cbl, and SHIP. Together, these pathways influence the expression and activity of a variety of proteins including transcription factors (GATA-1, NF-E2, SCL, NF- κ B, and Forkhead) and proto-oncogenes that participate in regulation of cell survival, proliferation, and differentiation.

Tpo Receptor

Expression

Tpo is the primary physiological hormone, which regulates all aspects of megakaryocyte and platelet development. Tpo interacts with its receptor, Mpl, on the cell surface of megakaryocyte precursors, mature megakaryocytes, and platelets to stimulate megakaryocyte progenitor proliferation and maturation, megakaryocyte polyploidy, and induction of platelet-specific proteins. The biological activity of the Mpl receptor is not limited to the megakaryocytic lineage. Unlike Epo or G-CSF, Tpo exerts profound effects on the proliferation of primitive hematopoietic cells through expression of Mpl on early hematopoietic progenitor cells of all lineages.

Signaling pathways activated by Tpo

Upon binding of Tpo to its receptor, Mpl, a number of signaling events are triggered, which are very similar to those of activated Epo-R. Binding of Tpo to Mpl induces the formation of an active dimer, enabling the associated JAK2 kinases to transphosphorylate each other. Activation of JAK2 results in

phosphorylation of two of five tyrosines in the cytoplasmic region of Mpl. Proteins recruited to these sites include STAT3 and STAT5, Shc, Grb2, SOS, and Vav. Signaling pathways that are activated include those of Ras, MAPKs, and PI 3-kinase/Akt, as well as negative regulatory pathways through tyrosine phosphatases including SH-PTP1 and the SOCS family. The distinction between intracellular signals of Tpo which promote hematopoietic stem cell expansion versus megakaryocyte development and platelet production are unknown.

G-CSF Receptor

Expression

The receptor for G-CSF, G-CSF-R, regulates the proliferation and differentiation of myeloid progenitors to form neutrophilic granulocytes, enhances the effector functions of mature neutrophils, and promotes their survival. In the hematopoietic system, G-CSF-R is expressed on myeloid progenitor cells, mature neutrophils, monocytes, and platelets. G-CSF-R expression increases with neutrophil differentiation. G-CSF-R is also expressed on endothelial cells, where it is thought to induce proliferation as well as migration, and on other nonhematopoietic cells including placenta, neuronal cells, activated T-lymphocytes, and cardiomyocytes.

Signaling pathways activated by G-CSF

G-CSF-R binds G-CSF as a homodimer. Unlike the other single-chain cytokine receptors, G-CSF-R activates multiple JAK kinases including JAK1, JAK2, and TYK2. Once activated, the JAK kinases induce phosphorylation of receptor tyrosines, which become docking sites for multiple SH2-containing signaling proteins as well as STAT1, STAT3, and STAT5. Pathways activated by G-CSF-R include those leading to activation of Ras, MAPKs, and Akt. Negative regulation occurs through the phosphatase SH-PTP1 and through SOCs. Experiments with G-CSF-R lacking one or more of the four cytoplasmic tyrosines suggest that pathways that regulate proliferation, differentiation, or survival differ, and characterization of these differences have important implications for understanding disorders of granulopoiesis.

GM-CSF/IL-3/IL-5 Receptors

Expression

The granulocyte/macrophage CSF (GM-CSF), interleukin-3 (IL-3), and IL-5 receptors are a subfamily of class I hematopoietin receptors. They have unique ligand-binding alpha chains but share a common beta chain (β_c), also called gp140. Many factors contribute to specificity in signaling between these receptors; one of these is that they are differentially expressed. Both the GM-CSF-R and the IL-3R are expressed on hematopoietic stem cells, and on the progenitors/precursors of neutrophils, macrophages, erythrocytes, megakaryocytes, and eosinophils. The IL-3R is expressed earlier in myeloid development than the GM-CSF-R. IL-3 promotes the expansion of the CD34⁺ multipotential progenitors and hematopoietic proliferation to a greater extent than GM-CSF, and promotes the development of a broader range of lineages that GM-CSF including monocytes, eosinophils, basophils megakaryocytes, mast cells, and

lymphoid cells. The GM-CSF receptor preferentially induces differentiation. By contrast, IL-5R expression is restricted to eosinophils, basophils, and mouse B cells. The IL-3 receptor subfamily is expressed on nonhematopoietic cells, but the *in vivo* significance is uncertain. Study of the crystal structure of the GM-CSF-stimulated receptor revealed a hexameric complex consisting of two GM-CSF molecules, two GM-CSF receptor α chains, and two β_c chains, which associate through a sequential process that is conserved among many other heterodimeric hematopoietin receptors.

Signal Transduction through the GM-CSF/IL-3/IL-5 Receptor

The common β_c subunit does not bind ligand by itself. Instead, β_c executes two critical functions following ligand binding. It enhances the ligand- α receptor binding from a low-affinity to a high-affinity interaction, and it functions as a major signaling component. The α chain may preassociate with β_c , but increased association occurs in the presence of ligand. Ligand binding increases oligomerization, creating clusters of two α and two β_c chains, the functional complex, or even larger complexes. Ligand binding facilitates formation of a disulfide linkage between α and β_c , not observed with the single-chain receptors. The β_c subunit elicits many signaling events, although the α chain is also required for signal transduction. There are eight tyrosine residues present on human β_c and proteins with SH2-binding domains that bind to the phosphorylated tyrosine residues largely determine the function of different receptor regions. The membrane proximal cytoplasmic region of β_c constitutively or inducibly associates with JAK kinases, predominantly JAK2, and is involved in induction of proliferation. The mid-region is necessary for promotion of viability, and the distal region is involved in growth inhibition. Receptor binding results in rapid activation/tyrosine phosphorylation of JAK2, β_c , and other JAK substrates. Downstream pathways activated include multiple STATs (1,3,5,6), Src kinases, Ras, MAPKs, PI 3-kinase, and Akt. Differences in signaling which result in the stimulation of different lineages, and proliferation versus differentiation or survival signals still require definition. For GM-CSF-R, which may serve as a model for some other hematopoietin receptors, exposure to low concentration of GM-CSF resulted in β_c receptor serine phosphorylation and initiates cell survival, whereas higher concentrations promoted tyrosine phosphorylation of β_c associated with proliferation as well as enhanced survival.

Receptors in the IL-6 SubFamily

Receptors for IL-6, IL-11, cardiotropin-1, ciliary neurotrophic factor, oncostatin M (OM), and leukemia inhibitory factor (LIF) represent another class I hematopoietin subfamily. They have major roles in hematopoiesis and in acute-phase and immune responses. They consist of a unique, ligand-binding α subunit and a common β chain called gp130, which oligomerize in response to ligand binding to α to initiate signaling. Although gp130 is ubiquitously expressed, the types of cells that respond to a specific IL-6 family cytokine is limited by the restricted and tightly regulated expression of the α receptor subunit. IL-6R and IL-11R have their own α subunits which complex with gp130, whereas other IL-6 subfamily cytokine

receptor complexes signal through different combinations of gp130, LIFR, and OM-R. A soluble form of the IL-6R α chain can be produced following limited proteolysis of membrane bound IL-6R or alternative splicing of mRNA. This receptor (sIL-6R) is unusual because unlike most other cytokine receptors, it can bind to and activate gp130 on cells that do not express IL-6R α chain after IL-6 exposure, thereby initiating signaling. Early hematopoietic cells are among the cells which can respond to IL-6 in the presence of only sIL-6R. By contrast, a soluble receptor form of gp130 detected in human serum inhibited signaling triggered by sIL-6R/IL-6 but not membrane-bound IL-6R, and thus is hypothesized to function as a natural inhibitor able to prevent constitutive signaling from sIL-6R. Similar to the common IL-3 β_c and the IL-2R γ subunit, the shared gp130 subunit enhances the affinity of receptor binding and serves as a major signaling component. Like other members of the hematopoietin family, these receptors signal through JAK/STAT, Ras, MAPK, and PI 3-kinase cascades, and terminate or modulate signals through tyrosine phosphatases, the SOCS, and PIAS (protein inhibitors of activated STAT) proteins.

Receptors in the IL-2 Subfamily

The IL-2 family cytokines play a critical role in the development of the immune system and in modulation of lymphocyte activation including maintenance of tolerance. The IL-2 receptor itself is critical in development and homeostasis of regulatory T cells. The IL-2 receptor subfamily includes receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21, which share the γ_c chain of IL-2R. Receptors for IL-4, IL-7, and IL-9 consist of two subunits, a unique α subunit in addition to γ_c . Receptors for IL-2 and IL-15 have three subunits, a unique α subunit and shared IL-2R β and γ_c . The differential expression of IL-2-receptor subunits, mechanisms of activation, and *in vivo* function in immune regulation are complex and have been described in detail. The α subunit acts as the ligand-binding subunit, whereas the β and γ subunits function to enhance receptor affinity and play a predominant role in intracellular signal transduction. Many of the signal transducers utilized by these receptors are the same as for other hematopoietin receptors, except that this subfamily is one of the few to utilize JAK3. Understanding the dynamics of γ_c -containing receptor expression and their function is important in lymphocyte biology and in the use of cytokine therapies targeting these receptors, which may have a number of different clinical applications in immune modulation.

The Class II Hematopoietin Receptor Family

IFN receptors have been divided into several major groups including type I (IFN- α , IFN- β , IFN- ω , and others), which are vital for cells to initiate an antiviral response and innate resistance to infection; type II (IFN- γ), which are involved in regulation of specific immune responses; and type III (IFN- λ). As an example of interferon receptor activation, IFN- γ binds to ligand-binding IFN γ R1 subunits, followed by recruitment of IFN γ R2 subunits to initiate signal transduction events through

activation of associated JAKs. The active IFN- γ receptor consists of two IFN γ R1 and two IFN γ R2 subunits. IFN receptors signal through distinct combinations of JAKs through signaling cascades involving the STATs, MAP kinases, PI 3-kinase, and additional pathways. Many of the pathways leading to specificity of response need to be defined.

Human Diseases Associated with Defect in Hematopoietin Receptors or Their Signaling Pathways

Naturally occurring defects in hematopoietin receptors are associated with a number of human diseases, resulting in either reduction or enhancement of cell production depending on the genetic location. Natural mutations in the negative regulatory region of cytoplasmic domain of Epo-R have been identified in benign erythrocytosis, and mutations in MPL (Tpo receptor) in hereditary thrombocytosis. By contrast, defective expression or function of MPL is the cause of the majority of cases of congenital amegakaryocytic thrombocytopenia, a severe inherited thrombocytopenia in infants with absent megakaryocytes in bone marrow and severely low circulating platelet counts. Congenital neutropenia is a heterogeneous disorder of myelopoiesis associated with maturation arrest at the promyelocyte/myelocyte stage and with distinct molecular mechanisms involving defects in genes including those for neutrophil elastase and Hax-1. Acquired mutations in the G-CSF receptor define a group of patients with a significantly increased likelihood of developing leukemia. The mutations, often resulting in truncation of the G-CSF receptor C-terminal cytoplasmic region, are thought to disrupt granulocytic maturation. Defects in transducers in the signaling pathways of hematopoietin receptors can also result in significant clinical phenotypes. Loss-of-function mutations of the γ_c (IL-2 receptor subfamily), JAK3, or TYK2 genes result in immunodeficiency. Mutations and translocations in JAK genes leading to constitutive activation are associated with a number of hematological malignancies including myeloproliferative disorders, acute lymphoblastic leukemia, and acute myeloid leukemias. Aberrant expression of IL-6 or increased expression of sIL-6R is now recognized to play an important role in a number of inflammatory and autoimmune disorders, as well as cancer. Blocking the IL-6R with targeted antibody is a promising new treatment for rheumatoid arthritis and potentially certain other inflammatory diseases. Mutations of the γ_c chain in the subfamily of IL-2 receptors have been shown to be the cause of X-linked severe combined immunodeficiency. All mutant receptors are defective in activation of JAK3.

Glossary

Biradical bond A chemical bond characterized as a biradical, three-center four-electron bond.

Prosthetic group A chemical compound present in and is an integral part of an enzyme or protein that is not composed of amino acid residues.

Singlet oxygen An oxygen molecule having one electron in an excited state. Chemical notation: $O_2(^1\Delta g)$.

Soret band The most intense absorption band in heme proteins. Also referred to as the γ band.

The class of proteins known as heme proteins includes all proteins that contain a heme moiety as a prosthetic group, which may or may not be covalently bound to the protein. The class encompasses proteins with a wide range of functions. Based on their properties, they may be separated into the following three subclasses: (1) Proteins that bind oxygen reversibly. These proteins are designed to transport and/or store oxygen among or within various body tissues. (2) Proteins that bind oxygen and activate it. These proteins serve as enzymes, capable of catalyzing an extensive list of reactions. This group also includes the enzymes that react with hydrogen peroxide. (3) Proteins that are unable to bind oxygen, and serve as electron carriers or transporters.

Structural Properties of Heme Proteins

Heme proteins are strongly colored proteins, usually reddish-brown, which is due to the presence of the heme moiety. The heme moiety consists of a substituted protoporphyrin ring, containing a liganded iron atom. In many mammalian heme proteins, the protoporphyrin ring is protoporphyrin IX, shown in [Figure 1](#). Chelated iron, whether ferrous or ferric iron, preferentially forms six liganded structures. In the heme proteins, four of these ligands are formed with the nitrogen atoms of the four pyrroles in the protoporphyrin ring. The fifth ligand, often referred to as the proximal ligand, is formed by an amino acid residue of the protein. This residue is a histidine residue in the oxygen-carrying proteins – myoglobin and hemoglobin, where the bond with the oxygen molecule forms the sixth or distal ligand. In heme proteins that serve as enzymes, the fifth ligand may be formed by a histidine, cysteine, methionine, or tyrosine residue. In the electron-carrying cytochromes, both fifth and sixth ligands are occupied by amino acid residues.

Heme Proteins That Serve as Oxygen Carriers

Several heme proteins are specifically designed to bind oxygen reversibly. In higher animals these proteins are hemoglobin

and myoglobin. The function of hemoglobin is to take up oxygen in the lungs, and transport it to the various tissues in the body. Myoglobin, present in muscle tissues, takes up the oxygen from the hemoglobin and stores it until it is needed for the production of adenosine triphosphate (ATP) in the mitochondria.

One oxygen molecule binds to the iron atom of the heme moiety at the sixth position which is vacant in the deoxygenated form of these proteins. The nature of the Fe–oxygen bond has been the subject of many investigations, and is still a matter of some controversy. At the present time, it appears that the properties of the oxygenated forms of hemoglobin and myoglobin are best explained by assuming that the bond between the oxygen molecule and the heme iron is a biradical bond, stabilized by d–p orbital overlap.

Myoglobin

Function

Myoglobin serves as an oxygen storage protein in muscle tissues, where it also aids in the diffusion of oxygen into the tissues. Together with the cytochromes, it is responsible for the red-brown color of muscle. The protein is abundant in the heart and skeletal muscles of animals; and it is especially abundant in the muscles of diving mammals, such as whales and seals, where a high capacity for the storing of oxygen is essential.

Structure

The protein is a monomeric heme protein, consisting of a single chain of 153 amino acids, and a non-covalently bound heme moiety. The structure is that of a compact, globular protein, consisting of eight helices, with the heme moiety located in a cleft formed between helices C, E, and F ([Figure 2](#)). The fifth ligand to the heme iron is donated by the imidazole nitrogen of histidine residue F8 of the F helix. The sixth ligand is formed by the bound oxygen, whereas in deoxymyoglobin the sixth ligand is vacant.

The iron atom in myoglobin is in the ferrous state. Oxidation of the iron to the ferric form yields metmyoglobin, which is unable to bind oxygen, and is therefore no longer functional.

Figure 1 Chemical structure of iron-protoporphyrin IX (hemin).

Oxygen binding

Myoglobin has a high affinity for oxygen, as shown in [Figure 3](#). This fact allows muscle tissues to extract oxygen from the bloodstream.

Hemoglobin

Structure

Hemoglobin is one of the most widely studied proteins. Its structure consists of four subunits, normally an $\alpha_2\beta_2$ tetramer, and each containing a heme moiety with the iron in the ferrous state.

Each α chain consists of 141 amino acid residues, and the β chains have 146 residues each. The three-dimensional structure of the individual subunits is very similar to that of myoglobin, although the amino acid compositions are very different.

Figure 2 Molecular structure of myoglobin. The polypeptide chain consists of eight helices, designated by the letters A through H, linked by short, unordered regions. Amino acids are numbered by their relative position in the chain. Reprinted from Dickenson RE (1964) *The Proteins*, 2nd edn., vol. II, p. 634. San Diego, CA: Academic Press, with permission from Elsevier.

Figure 3 Oxygen saturation curves of hemoglobin (Hb) and myoglobin (Mb).

Oxygen binding

Allosteric effects

The tetrameric structure of the molecule is crucial to its biological function. Oxygen does not have a high affinity for deoxyhemoglobin. However, binding of a molecule of oxygen to one of the hemes causes the Fe atom, which is normally located somewhat above the plane of the heme ring, to be drawn into the plane, a distance of 0.04 nm. This relatively slight movement triggers a change in the protein conformation that is transmitted to the adjacent subunits, which in turn dramatically enhances the affinity of their heme groups for oxygen. The result is that the oxygen saturation curve of hemoglobin has a sigmoidal form, as shown in **Figure 3**. This strong cooperative effect among the four subunits assures that almost total oxygenation occurs when the hemoglobin passes through the lungs, and that the oxygen is effectively released in the body tissues. A similar change in the position of the heme iron occurs in myoglobin upon the binding of an oxygen molecule; in myoglobin, however, this change in position appears to be nonconsequential.

Bohr effect

The affinity for oxygen is also dependent on pH. Lower pH decreases the affinity for oxygen. This is known as the Bohr effect. This effect causes a better unloading of the oxygen in tissues with a high metabolic rate. Such tissues usually have a lower pH, because of the presence of acidic products, such as lactate, citrate, and malate.

Regulation by 2,3-diphosphoglycerate

Oxygen binding to hemoglobin is also regulated by the metabolite 2,3-diphosphoglycerate (2,3-DPG). 2,3-DPG is present in erythrocytes at a concentration similar to that of hemoglobin. Hemoglobin binds one molecule of 2,3-DPG per tetramer. Its regulatory effect on oxygen binding by hemoglobin is most evident when there is a change in altitude. At higher altitudes, where the partial pressure of oxygen is lower, 2,3-DPG binding compensates by shifting the oxygen saturation curve to the right.

Interaction with other compounds

In addition to oxygen, other compounds bind to the heme iron of hemoglobin and myoglobin. Among them are the

notorious compounds, that is, carbon monoxide and cyanide. Both compounds bind to the heme iron much more strongly than oxygen, thus preventing oxygen from binding. This is the basis for the high toxicity of these compounds, even at low concentrations.

Methemoglobin formation

The oxygen in oxyhemoglobin promotes a spontaneous oxidation of the ferrous hemoglobin to ferric hemoglobin or methemoglobin, which is unable to bind oxygen. During this reaction the oxygen is reduced to the superoxide radical, which subsequently dismutates to hydrogen peroxide:

Fortunately, an enzyme present in red cells, methemoglobin reductase, reduces the methemoglobin back to normal hemoglobin, whereas catalase, which is also abundant in erythrocytes, catalyzes the dismutation of hydrogen peroxide to oxygen and water. This mechanism, together with the fact that the oxidation to methemoglobin is rather slow, assures that under normal conditions the amount of methemoglobin present in the red cell is only a few percent of the total hemoglobin present.

Hemoglobin mutants

Fetal hemoglobin

A large number of mutant hemoglobins are known to exist, most of which are harmless modifications. Several, however, are of physiological importance. Most important among them is fetal hemoglobin or hemoglobin F (HbF), which contains two γ chains instead of two β chains. Its tetrameric constitution is thus $\alpha_2\gamma_2$, instead of the $\alpha_2\beta_2$ configuration of normal hemoglobin (HbA). The γ chain differs from the β chain in that a serine residue is present at position 143 instead of a histidine. This one amino acid substitution causes a shift in the oxygen affinity curve to the left, especially at the upper portion of the curve. Thus, HbF has a higher affinity for oxygen than HbA. This allows the fetus to extract oxygen from its mother's blood in the placenta. HbF is gradually replaced by HbA during the first several months after birth.

Sickle cell hemoglobin

Another well-known hemoglobin mutant is HbS, or sickle cell hemoglobin. In HbS the amino acid residues at position 6 in the β chains are valines rather than glutamic acid residues. This change causes the deoxy form of HbS to aggregate into insoluble fibers. The presence of these fibers distorts the shape of the erythrocytes from a disk-shaped into a sickle-shaped cell. Sickle cells are considerably more fragile than normal erythrocytes, which accounts for the observed anemia in sickle cell patients.

It is estimated that in the USA about 3 million people suffer from the disease, mostly people of African descent. The reason for the high survival rate of the mutant gene is that HbS provides protection against the malaria parasite, the greatest killer of all times. This parasite spends part of its life cycle in human erythrocytes. However, the HbS is apparently much

less suitable for the proper development of the parasite than HbA, thus protecting the sickle cell patients when malaria epidemics occur.

Blood substitutes

A considerable amount of research has been done recently on the modification of human and bovine hemoglobins in order to produce a suitable product to serve as a blood substitute. This requires a covalent cross-linking of the α and β chains in order to prevent dissociation of the tetramer. Initial clinical trials, however, revealed that hemoglobin can be quite toxic when it is present in large quantities in the circulation outside the confines of the red cell.

Heme Proteins That Serve as Enzymes

A considerable number of heme proteins are found in nature that serve as enzymes. These include most peroxidases and catalases, as well as a large group of monooxygenases generally referred to as the cytochrome P₄₅₀ enzymes. In addition, a few oxidases, hydrolases, and dioxygenases are heme enzymes. Peroxidases and catalases use hydrogen peroxide as the oxidizing agent. The cytochrome P₄₅₀ enzymes as well as the other enzymes catalyze oxidizing reactions that involve molecular oxygen, of which either one or both atoms are incorporated into a substrate.

Peroxidases

Structure and function

Peroxidases are a group of enzymes that catalyze the oxidation of a substrate by hydrogen peroxide or an organic peroxide. Most peroxidases are ferric heme proteins – one notable exception being the glutathione peroxidase, which is a selenium-containing enzyme. They are present in virtually all living species.

Most peroxidases are able to oxidize a variety of substrates of widely different structures, varying from halide ions to hydroquinones to aromatic azo compounds. A binding site for the substrate to be oxidized is therefore virtually absent in most of these enzymes. In fact, simple molecules consisting of 8–12 amino acids and a covalently linked heme moiety, with a histidine residue forming the proximal ligand, have considerable peroxidase activity. These compounds are known as microperoxidases. Furthermore, methemoglobin and metmyoglobin can effectively function as peroxidases, having about 5–10% of the activity of horseradish peroxidase.

Mechanism of action

The mechanism of action of the heme peroxidases is shown in Figure 4. The first step involves an oxidation of the enzyme by the peroxide, leading to the formation of a ferryl (Fe^{IV}) heme moiety and the removal of an electron from either the porphyrin ring or an amino acid residue of the protein. This intermediate is commonly referred to as compound I. Compound I can then react with a suitable substrate and promote a one-electron oxidation of the substrate. A one-electron oxidation of the substrate (such as the oxidation of a hydroquinone to a semiquinone) converts the enzyme to compound II, in which the

Figure 4 Mechanism of action of peroxidases.

heme is still in the ferryl form, but the original structure of the porphyrin ring or the amino acid residue is restored. Transfer of a second electron from compound II to a substrate restores the native ferric enzyme.

The two arrows in compounds I and II represent the two unpaired electrons in the biradical bond between the iron and the oxygen atom. The '+' mark in compound I represents the positive charge on the porphyrin ring. AH_2 and $\text{AH}\cdot$ represent the substrate and the radical product, respectively.

Of the plant peroxidases, the enzyme from horseradish is perhaps the most studied. It is a 40-kDa monomeric enzyme, with a histidine residue as the proximal ligand. The functions of the peroxidases in plants appear to be the generation of free-radical intermediates that promote the polymerizations and cross-linkings necessary to form the cell-wall structures in plants. Enzymes present in the roots of plants are thought to protect the host against invading fungi and other microorganisms.

In mammals, the most studied peroxidases are myeloperoxidase present in neutrophils, eosinophil peroxidase present in eosinophils, thyroid peroxidase present in the thyroid gland, and lactoperoxidase present in milk and saliva. Except for the thyroid peroxidase, the function of all these peroxidases seems to involve a defense against invading microorganisms. The function of the thyroid peroxidase is the iodination of tyrosine residues during the synthesis of the hormone thyroxine.

Haloperoxidases

The mechanism by which myeloperoxidase exerts its antimicrobial activity has been largely elucidated by Seymour Klebanoff and his colleagues. The phagocytosis of a microorganism by a neutrophil activates a membrane-bound NADPH oxidase that excretes large amounts of hydrogen peroxide into the phagosome. The myeloperoxidase reacts with the H_2O_2 to form a compound I-type structure, which in turn oxidizes a chloride ion to hypochlorite (HOCl) in a reaction involving a two-electron transfer, similar to that of catalase. The hypochlorite formed is lethal to the microorganism. Lactoperoxidase uses a similar mechanism to kill bacteria present in milk or saliva; however, it uses either iodide or isocyanate as the ion to be oxidized. *In vitro*, these enzymes exert a cytolytic activity against most cells, prokaryotic as well as eukaryotic.

Other peroxidases that are capable of oxidizing halide ions include chloroperoxidase present in certain molds. This enzyme carries out organic chlorination reactions, presumably through the formation of an intermediate enzyme-bound form of hypochlorite.

Reactive oxygen species

An increasing number of the heme enzymes have recently attracted attention, because of their alleged involvement in the generation of reactive oxygen species (ROSs). ROSs are implicated in causing damage to DNA, RNA, lipids, and proteins, and may be directly or indirectly involved in the initiation of cancer, as well as diseases such as Alzheimer's, Parkinson's, multiple sclerosis, and other diseases involving tissue degeneration and cell death. ROSs include superoxide, hydrogen peroxide, the hydroxyl radical, singlet oxygen, and ozone.

It should be clear from the above description that peroxidases are enzymes specifically designed to generate free-radical products. Compounds I and II have oxidative energies comparable to that of the hydroxyl radical, and the products generated by these enzymes often are free radicals. These products, in turn, can promote polymerization reactions of proteins and lipids. Furthermore, it is known from *in vitro* experiments that most, if not all, peroxidases are able to exert cytolytic activities under appropriate conditions. It is also known that both myeloperoxidase and chloroperoxidase are able to generate singlet oxygen. These observations support the hypothesis that peroxidases may be involved in at least some of the tissue damage that is presently ascribed to the actions of ROSs.

Catalases

Structure and function

Catalases are enzymes designed to neutralize the hydrogen peroxide that is formed *in vivo* by various oxidases and other enzymes. The enzyme catalyzes the dismutation of 2 mol of hydrogen peroxide into 1 mol of oxygen and 1 mol of water:

Catalases are found in all aerobic cells; in fact, in some bacteria catalase may account for as much as 1% of their total dry weight. High concentrations are also present in erythrocytes, where it serves to neutralize the hydrogen peroxide formed during the autoxidation of oxyhemoglobin to methemoglobin. Catalases are among the enzymes with the highest turnover rates known: under optimal conditions each subunit can dismutate 2×10^5 mol of hydrogen peroxide per second.

Catalases in eukaryotes are tetramers, each subunit containing a ferric heme and a bound molecule of NADPH. The reason for the presence of this coenzyme is still unclear at this time. In the catalases, a tyrosine residue forms the proximal ligand to the heme iron.

Mechanism of action

Their mechanism of action is somewhat similar to that of the peroxidases. Upon binding of a mole of H_2O_2 , a compound I-type intermediate is formed, and a mole of water is released. The enzyme then reacts with a second mole of H_2O_2 to form a mole of oxygen and the native enzyme is regenerated (Figure 5). No radical intermediates are formed by catalases.

Figure 5 Mechanism of action of catalases.

Oxygenases

Oxygenases are a group of heme enzymes that catalyze the oxidation of various substrates by molecular oxygen. Certain oxygenases catalyze the incorporation of both oxygen atoms into the substrate; these are referred to as dioxygenases. Others catalyze the incorporation of one atom of oxygen into the substrate, while the other atom is reduced to water. This group constitutes the monooxygenases.

Almost all of the dioxygenases do not contain heme; non-heme iron sulfur groups form their active center. An example of a heme-containing dioxygenase is tryptophan dioxygenase.

Monooxygenases are also referred to as mixed-function oxygenases or hydrolases. In addition to molecular oxygen, this group of enzymes requires the presence of a co-substrate capable of donating a pair of electrons to reduce the second atom of oxygen to water. A typical monooxygenase reaction is the hydroxylation of an alkane to an alcohol:

in which R represents the co-substrate. Many compounds can serve as a co-substrate for the monooxygenases; these include the pyridine nucleotides, flavins, ferredoxins, hydroquinones, ascorbate, and others.

Cytochromes P₄₅₀ Enzymes

The cytochrome P₄₅₀ enzymes are a special group of monooxygenases, all of which use NADPH as the co-substrate. The name of this group of enzymes is associated with their discovery, when it was noted that, in the presence of carbon monoxide, their absorption spectrum resembles that of the known cytochromes, with the maximum absorbance of the Soret band located at about 450 nm. Functionally, however, they are not related to the group of proteins normally known as cytochromes.

Occurrence

The cytochrome P₄₅₀ family of enzymes is present in all living species. They have been isolated from bacteria, yeasts, plants, insects, as well as from vertebrate animals, where they are present in a large number of tissues. In fact, a list of the sequences of 325 different cytochrome P₄₅₀'s is presented in Ortiz de Montellano's book *Cytochrome P450*, and many more have been identified since then.

Functions

The cytochromes P₄₅₀ comprise a large group of enzymes that are able to incorporate one of the two atoms of an oxygen

molecule into a broad variety of substrates, with the concomitant reduction of the other oxygen atom to water. Members of the family are known to catalyze hydroxylations, epoxidations, N-oxidations, N-, S-, and O-dealkylations, sulfoxidations, dehalogenations, and other reactions.

The two main functions of the cytochrome P₄₅₀ enzymes appear to include first the control of the steady-state level of endogenous effectors of growth and differentiation. As such, they are important in the metabolism of numerous physiological substrates, including prostaglandins, steroids, cytokines, bile acids, fatty acids, and biogenic amines. Second, they metabolize a wide range of foreign chemicals, including environmental pollutants, drugs, various natural plant products, and many other foreign materials that enter the body.

Mechanism of action

The enzymes contain a heme moiety with iron in the ferric state, and with a cysteine residue as the proximal ligand. Oxygen binds as the sixth ligand. The principal catalytic cycle of the cytochrome P₄₅₀ enzymes for a hydroxylation reaction is shown in **Figure 6**. The first step involves a binding of the substrate XH to the enzyme. In step 2, the ferric enzyme is reduced to the ferrous form with an electron obtained from the co-substrate NADPH. The ferrous enzyme then binds a molecule of oxygen in step 3. In step 4, a second electron from NADPH is used to reduce the oxygen molecule, which leads to the uptake of two protons, the release of a molecule of water, and the formation of a compound I-type ferryl enzyme. In the final step, the oxygen atom of compound I is incorporated into the substrate,

Figure 6 Principal catalytic cycle of cytochrome P₄₅₀ enzymes. XH, substrate; XOH, product.

and the product is released. Steps 4 and 5 probably constitute a series of individual steps; however, they occur so fast that they cannot be observed with present-day's techniques.

Heme Proteins That Serve as Electron Carriers

Cytochromes

Function

The cytochromes, with the exception of the members of the cytochrome P₄₅₀ family, are heme proteins, designed for the transport of individual electrons. Their heme moiety is normally enveloped by the protein portion, excluding it from contact with the outside solvent. The transport of individual electrons is facilitated by an oscillation of the heme iron between the ferrous and the ferric forms. The flow of electrons from the outer edge of the cytochrome to the heme iron may involve the participation of one or more amino acid residues (e.g., tyrosines). The driving force for the movement of electrons is provided by the differences in redox potential between the electron donor and the acceptor.

Cytochromes are identified by the type of heme moiety present (a, b, c, or d), and the wavelength of maximal absorbance of the Soret band (e.g., cytochrome b₅₅₉). The four heme moieties differ in the structure of the side chains of the porphyrin ring.

Cytochromes c

c-Type cytochromes are found in animals, plants, and eukaryotic microorganisms. They are the only type cytochromes that are water soluble. They are monomeric proteins, containing a heme c moiety, with the proximal and distal ligands formed by histidine and methionine residues. They usually contain a single heme per molecule; however, molecules containing up to eight heme residues are found in certain photosynthetic bacteria. The best-known and most-studied member of this group is the mitochondrial cytochrome c, which transports electrons from complex II to complex III in the electron transport system.

Cytochromes b

b-Type cytochromes are widely distributed. They are present in bacteria, chloroplasts, and mitochondria. The mitochondrial b-type cytochromes are normally embedded in membranes as part of complex II of the electron transport system. They contain a protoheme with histidine in both the proximal and distal ligand positions. The function of all b-type cytochromes appears to be to transport electrons from dehydrogenases to cytochrome c-type proteins or to iron-sulfur proteins.

Cytochromes a

a-Type cytochromes in mitochondria are an important part of the electron transport chain. They form an integral part of complex III, where they take up electrons from cytochrome c and pass them on to the copper ions and the bound oxygen in the cytochrome oxidase system.

Glossary

Erythroblast Erythroid cell precursor; nucleated cell in bone marrow that develops into an erythrocyte.

Erythrocyte A red blood cell; non-nucleated, disk-shaped blood cell that contains hemoglobin.

Erythroid Erythrocyte related.

Erythropoiesis Formation and production of erythrocytes.

Tetrapyrrole A general term that refers to molecules with four rings of the pyrrole type, most often linked together by single-atom bridges between the α -positions of the five-membered pyrrole rings. The arrangement of the four rings is macrocyclic in porphyrins.

Introduction

Heme, a four-ring organic compound with a central iron atom, plays multiple roles in cellular processes. For example, it is the crucial component in hemoglobin, a red blood cell protein responsible, in vertebrates, for the transport of oxygen from the lungs to the different tissues and the transport of carbon dioxide from the tissues to the lungs. It is heme that gives the characteristic red color to blood. Given its importance in many vital functions in organisms ranging from bacteria to man, it is not surprising that most cells synthesize heme. However, in humans, differentiating erythrocytes represent the major site of heme production due to the synthesis of hemoglobin, which accounts for ~85% of the total heme.

Heme Structure

The observation that hemoglobin can be split into two components, with the smaller unit corresponding to the compound which today is recognized as heme, was made by L R LeCanu in 1837. While the correct structure of heme was initially proposed by Kuster in 1912, it only received general acceptance 16 years later upon its chemical synthesis. The Nobel prize-winning organic chemist Hans Fischer developed syntheses leading to the assembly of four rings, or pyrroles, into a macrocyclic structure with a purple-red color, which he appropriately named 'porphyrin' (from the Greek porphuros, meaning purple). The chemically synthesized porphyrin, which had properties identical to those of the natural porphyrin (derived from heme upon the release of the iron atom), was designated protoporphyrin IX. Thus, heme consists of four rings (pyrroles), composed of carbon, nitrogen, and hydrogen atoms, linked together in a cyclic array and containing an atom of iron in its center (Figure 1).

Heme is now recognized as a member of a large family of metalated tetrapyrroles, which are essential for life on Earth. They include chlorophylls, cobalamin (vitamin B₁₂), siroheme, and coenzyme F₄₃₀. Chlorophylls trap the light energy required in photosynthesis. Cobalamin-containing enzymes catalyze intramolecular rearrangements, methylations, and reduction of ribonucleotides to deoxyribonucleotides. Siroheme is an essential component of enzymes involved in

sulfur and nitrogen metabolisms. Coenzyme F₄₃₀, present in methanogenic bacteria, functions in methane formation. While the central metal ions in these tetrapyrroles differ – Fe²⁺ in the case of heme and siroheme, Mg²⁺ in chlorophyll and bacteriochlorophyll, Co²⁺ in cobalamin, and Ni²⁺ in coenzyme F₄₃₀ – the unifying feature is the presence of a complexed metal ion, which promotes a remarkable number of different biochemical reactions. Further, the protein scaffold binding the metalloporphyrin modulates the chemistry (redox state and coordination properties) of the metal ion, such that the spectrum of the reactions expands beyond the normal properties of the metal ion. It is this interplay between the protein moiety and the metalloporphyrin that provides the plethora of functions associated with metalloporphyrin-containing proteins.

The Heme Biosynthetic Pathway

Formation of 5-Aminolevulinate

The biosynthesis of tetrapyrroles is initiated from simple molecules and comprises only a few enzymatic steps (Figure 2). The first committed precursor, 5-aminolevulinic acid (ALA), is synthesized from either succinyl-CoA or glutamate, and thus the names C4 and C5 (based on the number of carbon atoms in the precursor), for the two ALA biosynthetic pathways evolved in nature. In most nonphotosynthetic eukaryotes and a few prokaryotes (i.e., the α -proteobacteria), ALA results from the condensation between glycine and succinyl CoA (C4 pathway), while in plants and most bacteria, ALA is derived from glutamate (C5 pathway). The C4 pathway requires a single enzyme, ALA synthase (ALAS); by contrast, three enzymes are involved in the conversion of glutamate into ALA. Specifically, glutamyl-transfer RNA (tRNA) synthetase converts glutamate to glutamyl-tRNA, which is reduced by glutamyl-tRNA reductase to glutamyl-1-semialdehyde (GSA); this product is then transformed by GSA aminomutase or GSA aminotransferase (GSA-AT) to ALA. Pyridoxal 5'-phosphate, a vitamin B₆-derivative, is an essential component (cofactor) of both ALAS and GSA-AT, as these enzymes cannot function relying solely on the protein moiety. Among prokaryotes, ALAS is only found in the α -proteobacteria, which are considered to be the most closely related, free-living organisms to the

Figure 1 Iron-protoporphyrin IX, which is commonly designated as heme. Iron-protoporphyrin IX (or heme) has an iron ion complexed with the conjugated, aromatic porphyrin ring and an asymmetrical side-chain substitution. Note the $-\text{CH}_3$ (methyl), $-\text{CH}=\text{CH}_2$ (vinyl), and $-\text{CH}_2-\text{CH}_2-\text{COOH}$ (propionate) groups as side chains.

ancestral progenitor of the mitochondrion. Thus, it is conceivable that eukaryotic ALASs were acquired from a free-living α -proteobacterium during its transformation, first to an endosymbiont and subsequently to a mitochondrion.

From ALA to Uroporphyrin III

In eukaryotes, the first and three final enzymatic steps of heme biosynthesis occur within mitochondria, while the intervening four occur in the cytosol (**Figure 2**). Once ALA is made and transported to the cytosol, through most likely a specialized mitochondrial transporter, two molecules of ALA are asymmetrically condensed to form the monopyrrole porphobilinogen (PBG) by PBG synthase (PBGs; also known as ALA dehydratase). PBG constitutes the building unit of tetrapyrroles and hence eight molecules of ALA are required to form one heme molecule. Crystal structures of PBGs from different species have confirmed the presence of two distinct binding sites for each ALA molecule, termed A and P to distinguish the two ALA substrate molecules. The A-side of ALA forms the acetyl half of PBG, leaving its amino group intact, while the P-side of ALA

forms the propionyl half of PBG with the amino group becoming part of the PBG ring. PBGS has a homo-octomeric structure composed of four dimers, and each subunit contains an active site metal ion (zinc or magnesium and/or potassium depending on the species) and in many cases an allosteric metal ion (magnesium). The next step in heme biosynthesis involves the deamination and stepwise polymerization of four PBG molecules by PBG deaminase to give the linear tetrapyrrole 1-hydroxymethylbilane. Then, uroporphyrinogen III synthase catalyzes the cyclization of the linear tetrapyrrole, whereby the D ring of hydroxymethylbilane is inverted to generate the asymmetrical macrocycle, uroporphyrinogen III. In the absence of uroporphyrinogen III synthase, 1-hydroxymethylbilane cyclizes into the nonphysiological relevant tetrapyrrole, uroporphyrinogen I. The incredible acrobatics that must occur with the flipping of the D ring and closure of hydroxymethylbilane speak for the importance of uroporphyrinogen III synthase in making uroporphyrinogen III synthesis reaction. In fact, disastrous consequences emerge with the malfunction of uroporphyrinogen III synthase, as observed in patients with the blood disorder congenital erythropoietic porphyria, who typically have high levels of uroporphyrinogen I and derivatives thereof.

From Uroporphyrinogen III to Protoporphyrinogen IX

For most eukaryotes, the last cytosolic step is the sequential decarboxylation of the four acetate side chains of uroporphyrinogen III to methyl groups by uroporphyrinogen decarboxylase (Figure 2). This enzyme is a $(\alpha/\beta)_8$ barrel protein, which appears to be functional as a homodimer and not to require prosthetic groups or cofactors. Remarkably, uroporphyrinogen decarboxylase enhances the rate of substrate decarboxylation by a factor of 1.2×10^{17} , one of the largest rate enhancements reported for an enzyme that functions without the help of cofactors. The uroporphyrinogen decarboxylase-catalyzed reaction gives coproporphyrinogen III, which is the substrate of coproporphyrinogen oxidase (CPO). The oxidative decarboxylation of the propionate side chains of the rings A and B of coproporphyrinogen III yields protoporphyrinogen IX. While eukaryotic CPO activity depends on oxygen, prokaryotic organisms, under anaerobic conditions, use alternative electron acceptors in the oxidative decarboxylation reaction. Hence, oxygen-independent CPOs (HemN and HemZ, i.e., the products of the *hemN* and *hemZ* genes) are found in bacteria; indeed, facultatively anaerobic bacteria, such as *Escherichia coli*, possess both oxygen-dependent CPO (HemF) and oxygen-independent CPO (HemN). HemN contains an iron-sulfur center ($[4\text{Fe}-4\text{S}]$), which is essential for the activity of the enzyme in conjunction with nicotinamide adenine dinucleotide (phosphate), reduced (NAD(P)H) and S-adenosyl-L-methionine (SAM). As one would expect, the enzyme appears to have a distinct reaction mechanism with the involvement of SAM in the formation of a radical, and thus HemN has been aptly identified as a radical SAM enzyme. As far as the subcellular location of the oxygen-dependent CPO goes, it seems to vary! In mammals and other higher eukaryotes, it appears to be associated with the inner side of the mitochondrial outer membrane, whereas in the yeast *Saccharomyces cerevisiae* and bacteria it is found in the cytosol.

From Protoporphyrinogen IX to Heme

In the penultimate step, protoporphyrinogen oxidase (PPO) catalyzes the complete aromatization of protoporphyrinogen IX ring into protoporphyrin IX, which involves a six-electron oxidation (Figure 2). Similar to CPO, anaerobic and facultative anaerobic bacteria have an oxygen-independent PPO; however, in contrast to CPO, facultative anaerobic bacteria possess solely an oxygen-independent PPO (and not in complementation with an oxygen-dependent PPO). All other organisms appear to have PPOs, which use oxygen as the terminal electron acceptor. Ferrochelatase catalyzes the terminal step of the heme biosynthetic pathway, the insertion of ferrous iron into the protoporphyrin IX macrocyclic ring. Eukaryotic ferrochelatases associate with the inner side of the mitochondrial inner membrane, and vertebrate enzymes have a $[2\text{Fe}-2\text{S}]$ cluster (although this is not an exclusive structural feature of vertebrate ferrochelatases). The mechanism of the ferrochelatase reaction involves an out-of-plane distortion of the porphyrin, which facilitates the reaction by exposing the pyrrole nitrogens to the incoming ferrous iron substrate.

Regulation of the Heme Biosynthetic Pathway/Heme Biosynthesis

There is not a single ubiquitous regulatory mechanism for heme biosynthesis, and so the discussion in this article focuses solely on the regulation of the pathway in mammalian cells. Considering that heme is predominantly synthesized in bone marrow (i.e., in erythroblasts and reticulocytes that still contain mitochondria) and liver cells, most of the studies on regulation have focused on these two types of cells. Predominance of heme synthesis in bone marrow and liver cells reflects the greater demands due to the syntheses of the heme-containing proteins, hemoglobin, and cytochrome P-450 enzymes, respectively. The major regulatory and rate-limiting step of the pathway corresponds to the reaction catalyzed by ALAS, the first enzyme of the pathway. Two genes, located in two different chromosomes in humans, encode the two ALAS forms of the enzyme (or isozymes): ALAS1 and ALAS2. The gene encoding ALAS1 is expressed in every cell, whereas that for ALAS2 is specifically expressed in erythroid cells. Importantly, the regulatory mechanisms for the expression of the two ALAS genes and the posttranscriptional events seem to be distinct in differentiating erythrocytes from those in nonerythroid cells. ALAS1 controls the production of heme for basic cellular functions and is feedback regulated by heme through (1) repression of transcription of the ALAS1 gene, (2) inhibition of translation of the ALAS1 message, (3) destabilization of the ALAS1 message, and (4) inhibition of import of the cytosolic precursor form of the enzyme into mitochondria. By contrast, certain drugs and hormones induce liver cells to make more ALAS, and consequently heme and cytochrome P-450, by activating transcription of the ALAS1 gene.

In differentiating erythroid cells, the syntheses of heme and globin need to be coordinated, as the production of hemoglobin requires that neither the protein (globin) component nor the nonprotein component (heme) will be in excess. And indeed, identical transcriptional elements have been identified

in the genes of ALAS2 and globin. Another level of regulation of the erythroid heme biosynthetic pathway is centered at the stage of translation, which responds to the cellular iron levels. This response is mediated through specific interactions between an iron-responsive element (IRE), present in the ALAS2 messenger RNA (mRNA), and IRE-binding proteins, such that under iron limitation, the translation of ALAS2 mRNA is inhibited, while the presence of iron above the cellular threshold relieves the repression caused by IRE-binding proteins. The essential requirement for ALAS2 in heme biosynthesis and erythropoiesis was clearly demonstrated with targeted disruption of ALAS2 in the mouse, which led to no hemoglobin in cells, the accumulation of iron (albeit in the cytoplasm and not in mitochondria) and, ultimately, embryonic death.

Heme Function

The known roles of heme are many and variable, and most probably many other functions await discovery. As referred to above, heme is a prosthetic group of proteins involved in oxygen transport such as hemoglobins and myoglobins, which are the major blood and muscle proteins, respectively. In addition, heme participates in other cellular processes including anaerobic and aerobic respiration, sensing of diatomic gases (e.g., nitric oxide and carbon monoxide), detoxification of foreign substances (e.g., drugs) by oxidative metabolism, and signal transduction. Some of these functions might also be coupled with the regulatory roles of heme in gene transcription, translation, microRNA (miRNA) processing, mitochondrial protein import, protein stability, and differentiation. A transcription factor that regulates the mammalian biological clock was also discovered to use heme as a cofactor to sense, and react to, changes in the cell, thus linking cellular metabolism with the biological clock. Another area of research has led to the emergence of a new proposal that heme deficiency or dysregulation is intimately associated with the aging process, including neural decay.

Disorders of the Heme Biosynthetic Pathway

Malfunction of the heme biosynthetic pathway can have disastrous consequences, and in humans it can be manifested in porphyrias. Briefly, porphyrias are disorders that result from inherited or acquired defects in the heme biosynthetic pathway. The first reports of porphyrias were in 1874. Since then, eight types of porphyrias associated with defects in each of the eight enzymes of the pathway have been identified (Table 1), and depending on the major site of expression of the enzymatic defect, they have been classified into hepatic or erythropoietic porphyria. Although the molecular mechanisms behind the clinical manifestations are not well understood, the two major symptoms include cutaneous photosensitivity and central nervous system disturbances, and thus the other classification of either photosensitive or neurological porphyrias. Some porphyrias, however, manifest overlapping symptoms. Photosensitivity is a result of porphyrin accumulation, which typically occurs when the defective enzyme is

Table 1 Heme biosynthesis-associated disorders

Disorder	Defective enzyme
X-linked sideroblastic anemia	5-Aminolevulinate synthase (erythroid)
X-linked dominant protoporphyria	5-Aminolevulinate synthase (erythroid)
ALA dehydratase, or Doss, porphyria	Porphobilinogen synthase (or ALA dehydratase)
Acute intermittent porphyria	Porphobilinogen deaminase
Congenital erythropoietic porphyria	Uroporphyrinogen III synthase
Porphyria cutanea tarda	Uroporphyrinogen decarboxylase
Coproporphyria	Coproporphyrinogen oxidase
Variegate porphyria	Protoporphyrinogen oxidase
Erythropoietic protoporphyria	Ferrochelatase

anywhere in the pathway beyond the third step of the pathway (i.e., the PBG deaminase-catalyzed reaction), whereas the neurologic manifestations are associated with overproduction of ALA and PBG. However, the first porphyria associated with erythroid ALAS, named X-linked dominant protoporphyria (XLDPP), was recently identified, and elevated concentration of ALA-derived protoporphyrin IX and Zn-protoporphyrin were observed in the erythrocytes of the XLDPP patients. Since the 1980s, many of the genetic mutations responsible for the enzymatic defects have been identified and mouse models, targeted to correct the defective enzyme, have been developed by engineering functional enzyme expression in bone marrow cells. Zebrafish have also provided powerful molecular models for erythropoietic porphyrias. For example, mutations in the ferrochelatase gene resulted in photosensitive zebrafish with autofluorescent blood. Finally, mutations in the gene encoding for the erythroid ALAS can cause X-linked sideroblastic anemia (Table 1), a blood disorder characterized by mitochondrial iron accumulation due to a reduction in heme biosynthesis destined for hemoglobin production in erythroblasts.

Hexokinase/Glucokinase

E Van Schaftingen, Université Catholique de Louvain, Brussels, Belgium

© 2013 Elsevier Inc. All rights reserved.

Glossary

Glucokinase Hexokinase that acts specifically on glucose; common designation of mammalian hexokinase IV.

Hexokinase Enzyme catalyzing the adenosine triphosphate-dependent phosphorylation of glucose and related hexoses (mannose, 2-deoxyglucose, and fructose) to their 6-phospho-derivative.

Mnemonic and slow transition models Kinetic models allowing one to explain the nonhyperbolic saturation curve of some monomeric enzymes, most particularly the sigmoid saturation curve of mammalian glucokinase. These models assume the existence of two conformations with distinct affinities for the substrate and that they interconvert slowly. Only the high-affinity conformation is endowed with catalytic activity in the mnemonic model.

Role of Phosphorylation in Sugar Utilization

In order to be utilized by cells, monosaccharides need to be transported across the plasma membrane and phosphorylated. In many bacteria, transport of glucose and other sugars is coupled to their phosphorylation by complex systems utilizing the high-energy phosphoryl donor phosphoenolpyruvate. By contrast, transport and phosphorylation – in this case, at the expense of adenosine triphosphate (ATP) – are catalyzed by separate proteins in eukaryotic cells and also to some extent in bacteria. Sugars are most often phosphorylated on their last carbon (D-glucose to glucose 6-phosphate; ribose to ribose 5-phosphate, etc.), although, in some cases, phosphorylation takes place on the first carbon (galactose, L-fucose, and fructose in liver).

Phosphorylation provides several advantages: it is an exergonic process, capable of concentrating metabolites inside the cells; it prevents leakage of metabolites across the plasma membrane and intracellular membranes; and it increases the potential binding energy of substrates to enzymes, thereby facilitating catalysis. The name ‘hexokinase’ (from hexose and the Greek word, *κινεειν*, to move) was coined by Otto Meyerhof to designate the enzyme that activates glucose, making it ready for fermentation by muscle extracts. Kinase was to become the word used to designate all ATP-dependent phosphorylating enzymes.

Reaction Catalyzed by Hexokinases

Hexokinases (EC 2.7.1.1) are defined as enzymes phosphorylating glucose and other closely related hexoses (mannose, 2-deoxyglucose, glucosamine, and fructose) on their sixth carbon. Glucokinases (2.7.1.2) catalyze the same reaction but with only glucose as a substrate. Glucokinases using adenosine diphosphate (ADP) or polyphosphate as phosphoryl donor have been described in archaeobacteria (*Pyrococcus furiosus* and *Thermococcus litoralis*) and even in mammals; these will not be discussed further here.

Hexokinases and glucokinases catalyze the transfer of the terminal phosphoryl group of ATP to the oxygen borne

by the sixth carbon of glucose. As with other kinases, the true phosphoryl donor is the ATP–Mg complex. Except for inosine triphosphate (ITP), other triphosphonucleotides are usually much poorer substrates than ATP. ADP is generated in the reaction, as well as a hexose 6-phosphate. The reaction is highly exergonic ($\Delta G^{\circ'} \approx -16.7 \text{ kJ mol}^{-1}$), which means that in practical terms it is irreversible, most particularly under intracellular physiological conditions ($\Delta G < -30 \text{ kJ mol}^{-1}$). However, reversibility of the reaction can be demonstrated *in vitro* provided the generated ATP and glucose are continuously consumed.

The reaction mechanism involves the formation of a ternary complex and an in-line transfer of the phosphoryl group from the donor to the acceptor without formation of an enzyme-bound covalent intermediate. Many studies have been devoted to the determination of the order of substrate addition and product release, without any emerging consensus. It is likely that most hexokinases and glucokinases may bind the substrates in any order to produce a reactive ternary complex, although some enzymes display a preferred order (e.g., glucose before ATP in the case of mammalian hexokinase IV).

Diversity of Hexokinases and Glucokinases

Eukaryotes usually have several hexokinases. The yeast *Saccharomyces cerevisiae* has two hexokinases (P_I and P_{II} or A and B) as well as a glucokinase (Table 1). All three enzymes have subunits of 50 kDa, the two hexokinases being dimers of 100 kDa. The two hexokinases share ≈75% sequence identity with each other and only ≈37% sequence identity with glucokinase from the same species. All three enzymes display hyperbolic saturation curves for their substrates and a K_m for glucose <1 mM. Both hexokinases A and B are inhibited by trehalose 6-phosphate, an intermediate in the formation of trehalose, which appears to play the role of a feedback inhibitor for this enzyme (equivalent to the role of glucose 6-phosphate with mammalian hexokinases).

Mammals are classically said to have four distinct hexokinases, designated I, II, III, and IV, or A, B, C, and D. A fifth one, named ‘HKDC1’ (hexokinase domain containing 1), is an

Table 1 Some well-studied hexokinases and glucokinases

	Approximate subunit size (kDa)	Number of subunits	K_m for glucose	Inhibitor	Tissular distribution
<i>Mammals</i>

uncharacterized protein sequence deduced from genomes. Hexokinases I–III are ≈ 100 -kDa monomeric proteins, which resulted from the duplication of an ancestral gene encoding a 50-kDa hexokinase. They are characterized by low K_m values for glucose ($<0.2 \text{ mM}$) and by their sensitivity to inhibition by physiological concentrations of glucose 6-phosphate. Hexokinase III has an extremely low K_m for glucose and is inhibited by high concentrations of this substrate. Only the C-terminal half of hexokinase I appears to be catalytically active, whereas both amino and carboxyl halves of hexokinase II are endowed with catalytic activity.

Hexokinase IV or D is a ≈ 50 -kDa protein that has a low affinity for glucose, a sigmoidal saturation curve for this substrate and is not inhibited by physiological concentrations of glucose 6-phosphate. It is, however, inhibited by glucokinase regulatory protein. It does catalyze the phosphorylation of other hexoses than glucose, but due to its low affinity for all hexoses (including glucose), its physiological action is restricted to the most concentrated one, glucose, which is also its best substrate. Furthermore, there is ample evidence that hexokinase D plays the role of a glucose sensor. This may explain the popularity of its designation as glucokinase, which however does not mean that this enzyme is closer to true (microbial) glucokinases than to hexokinases. As a matter of fact, hexokinase IV is closer to mammalian low K_m hexokinases than to any other hexokinases or glucokinases.

Distinct hexokinase isozymes are also found in insects (e.g., in *Drosophila melanogaster*) and plants. The starfish enzyme is a 50-kDa protein that is inhibited by physiological concentrations of glucose 6-phosphate, indicating that this property is not limited to the 100-kDa enzymes.

Prokaryotes typically contain a series of specific hexokinases that each act on one hexose, normally glucose, mannose, or fructose. They are often composed of two subunits with a smaller size (20–35 kDa) than the eukaryotic enzymes.

There are, however, examples of true hexokinases in bacteria (e.g., the hexokinase of the archaeobacterium *Thermoproteus tenax*) or of enzymes catalyzing the phosphorylation of two hexoses but not glucose (e.g., mannofructokinase).

Classification and Evolution of Hexokinases

Sugar kinases can be classified into three distinct families (hexokinase, ribokinase, and galactokinase) of enzymes that differ in their three-dimensional structures and show no significant similarity. In the hexokinase family, the eukaryotic enzymes form a distinct subfamily of enzymes sharing $>30\%$ sequence identity. The hexokinase family also comprises bacterial enzymes acting on various substrates (hexokinases, glucokinases, mannokinases, fructokinases, and *N*-acetylmannosamine kinases) that are very distantly related to eukaryotic hexokinases.

The ancestral eukaryotic hexokinase was probably a 50-kDa protein (Figure 1). Early and late duplication events in the fungi lineage led to the appearance of yeast glucokinase and of the more closely related hexokinases A and B. In vertebrates, hexokinase IV (glucokinase) separated from hexokinases I–III before the gene duplication and fusion event that led to the 100-kDa enzyme. Hexokinase III branched off earlier than the duplication event that led to hexokinases I and II, consistent with the closer kinetic properties of the latter two enzymes compared to hexokinase III.

Three-Dimensional Structure

Yeast hexokinase A and B structures were among the first such structures determined during the 1970s. Yeast hexokinase has a bilobar structure with a large (primarily C-terminal) and a small (primarily N-terminal) lobe that are connected by a

Figure 1 Evolutionary relationship between some eukaryotic hexokinases and glucokinases. Hk, hexokinase.

Figure 2 Three-dimensional structures of yeast hexokinase (a) and human glucokinase (b). The structures shown are those of *Saccharomyces cerevisiae* hexokinase B (P-II) isozyme in its open conformation and human glucokinase in its closed conformation. Glucose-binding residues are shown as space-filling models in yeast hexokinase. Glucose (black) and an ATP analog (gray) are shown as space-filling models in human glucokinase. The location of the binding site for glucokinase activators is also indicated. From Kuser PR, Krauchenco S, Antunes OA, and Polikarpov I (2000) The high resolution crystal structure of yeast hexokinase PII with the correct primary sequence provides new insights into its mechanism of action. *Journal of Biological Chemistry* 275: 20814–20821.

hinge region. Both domains are made of β -sheets of similar topologies, flanked by α -helices (Figure 2). These are more abundant and larger in the C-terminal domain, accounting for its larger size. Between the two lobes is a deep crevice where the catalytic site resides. The enzyme exists under two distinct conformations, described as open and close, which differ by the diedral angle between the two lobes.

The glucose-binding site comprises side chains of extremely conserved residues of the hinge region (Asp211 in hexokinase B), the large lobe (Asn237, Glu269, and Glu302) and the small lobe (Ser158, Thr172, and Arg173). Binding of glucose to the large lobe induces closure of the catalytic cleft, allowing glucose to

contact the small lobe as well. The conformational change induced by this substrate is thought to facilitate the subsequent phosphoryl group transfer, being a nice illustration of the induced-fit theory. This theory is also supported by the observation that lyxose, a five-carbon substrate analog lacking the hydroxymethyl group that normally serves as phosphoryl acceptor, stimulates by ≈ 30 -fold the hydrolysis of ATP to ADP and Pi catalyzed by yeast hexokinase.

The binding site of hexokinases for ATP has been initially inferred from structural analogy of hexokinase with glycerokinase, HSP-ATPase, and actin, enzymes that have a similar bilobar architecture as hexokinase. It was confirmed by

site-directed mutagenesis and later by crystal structures with ATP analogs. ATP binds mainly to the larger domain, almost parallel to its main axis, with the gamma-phosphate group pointing to the hinge region.

The crystal structures of human hexokinase I and of the enzyme from *Schistosoma mansoni*, a glucose 6-phosphate-sensitive enzyme, are fundamentally the same as the structure of yeast hexokinase, repeated twice in the case of the mammalian enzyme. This is also true for mammalian glucokinase (Figure 2). The human and *S. mansoni* hexokinases were also crystallized as complexes with glucose 6-phosphate, showing that the binding site for this inhibitor overlaps with the putative ATP-binding site.

Mammalian Low- K_m Hexokinases

The activity of the low K_m hexokinases cannot be regulated by the glucose concentration in tissues or cell types (human erythrocytes) where the glucose concentration is well above their K_m . In other cell types (e.g., the adipocytes), their activity may well be controlled by the glucose concentration and therefore by glucose transport. There is, however, still a large degree of uncertainty as to the glucose concentration and the rate-limiting aspect of glucose transport in several cell types.

Inhibition by Glucose 6-Phosphate

Hexokinases I–III are inhibited by glucose 6-phosphate in a noncompetitive manner with respect to glucose, but competitive versus ATP. Inhibition by glucose 6-phosphate takes place at physiological concentrations, which argues for its physiological significance. It is antagonized by inorganic phosphate in the case of hexokinase I, but not of hexokinase II. This inhibition involves a site distinct from the glucose-binding site, as indicated by the finding that the phosphorylation products (mannose 6-phosphate and 2-deoxyglucose 6-phosphate) of several good substrates for hexokinase I are poor inhibitors compared to glucose 6-phosphate. At one time, it was thought that the (catalytically inactive) aminoterminal half of hexokinase contained the glucose 6-phosphate allosteric site; however, the realization that the isolated carboxyterminal half of the enzyme, as well as starfish hexokinase (a 50-kDa enzyme), was sensitive to glucose 6-phosphate inhibition argued against this hypothesis. Structural studies indicate that glucose 6-phosphate binds to the two halves of hexokinase I, in positions that overlap the putative ATP-binding sites. This agrees with the fact that the inhibition by glucose 6-phosphate is competitive versus ATP but not versus glucose. Site-directed mutagenesis experiments suggest, however, that the binding of glucose 6-phosphate to both sites may contribute to inhibition in hexokinase I.

Subcellular Localization of Mammalian Hexokinases

Hexokinases are cytosolic enzymes, but hexokinases I and II bind to mitochondria through a N-terminal hydrophobic region that interacts with voltage-dependent anion channel (VDAC). VDAC, a porin present in the outer mitochondrial membrane, is involved in the transport not only of

low-molecular-mass solutes, but also of proteins such as cytochrome *c*, which escape mitochondria to elicit apoptosis. Hexokinase II, which is highly expressed in numerous cancer cells, exerts antiapoptotic effects through its binding to VDAC. Their proximity with the mitochondrial pore makes also that hexokinases I and II are closer to the main source of ATP and to the main sink for ADP, thus facilitating diffusion. Furthermore, binding of hexokinase I to mitochondria decreases its affinity for the inhibitor glucose 6-phosphate.

Hexokinase IV (Glucokinase)

Sigmoidal Kinetics

One intriguing aspect of glucokinase, a monomeric enzyme, is that it displays a sigmoidal saturation curve for glucose, with a Hill coefficient of 1.6. This is not due to the presence of a second, allosteric binding site for glucose on the glucokinase monomer, but because of the existence of an additional conformation compared to hexokinases with a hyperbolic saturation curve. This additional conformation is a super-open state (Figure 3), in which the small domain is disorganized. The super-open state presumably binds glucose with very low affinity and only slowly reverts to the open and closed states. Its formation from the open state also occurs slowly and only when glucose is not bound. This denotes that the low-affinity conformation predominates at low glucose concentration. Raising the glucose concentration has a twofold effect: (1) it increases the proportion of enzyme that is able to bind glucose with high affinity (i.e., the enzyme in the open conformation) and (2) it promotes binding of glucose to the open conformation as it would do for any other hexokinase. This twofold effect is at the basis of the sigmoidal saturation curve. The slowness of the conformational changes is critical in this model. Kinetic models of cooperativity based on slow conformational changes are known as 'mnemonical models' and 'slow-transition models'.

Figure 3 Kinetic model of glucokinase. For details, see text. A, ATP; G or Glu, glucose; G6P, glucose 6-phosphate.

The existence of a super-open state, with no or little affinity for glucose, explains also how glucokinase has a much lower apparent affinity for glucose compared to other hexokinases, while all its glucose-binding residues are the same as those present in low K_m hexokinases. The best proof for this is the identification of a series of synthetic glucokinase activators that decrease the K_m value from ≈ 8 mM to about 0.1 mM, increase V_{max} , and suppress cooperativity. These activators bind to the open and closed states of glucokinase, though not to the super-open state, such that the latter no longer exists when the activators are present at saturating concentrations. Thus, the activators make glucokinase behave as a low K_m hexokinase. Their binding site has been identified in the hinge region of this enzyme (Figure 2). Because of their effect on islet cells and liver glucokinase, they stimulate *in vivo* both insulin secretion and glucose uptake by the liver, making them potentially useful therapeutic agents for the treatment of diabetes.

Liver Glucokinase and Its Regulatory Protein

One of the main sites of glucokinase expression is the liver. This is in relation with the ability of this organ to store glucose as glycogen. Glucose transport across the plasma membrane of liver parenchymal cells, carried out by glucose transporter 2 (GLUT-2), is extremely rapid. Glucokinase may therefore play a regulatory role and indeed the low affinity that glucokinase displays for glucose is one of the mechanisms by which glucose uptake can be regulated by glucose concentration. In addition to this, glycogen metabolism is under the direct control of glucose, which binds to glycogen phosphorylase, thereby affecting the phosphorylation state of this enzyme and glycogen synthase.

Hepatic glucokinase is controlled by a glucokinase regulatory protein (GCKR), which binds to glucokinase and inhibits it in a competitive manner with respect to glucose. Association of the two proteins is stimulated by fructose 6-phosphate, a GCKR ligand, which behaves therefore as an inhibitor of glucokinase, and antagonized by fructose 1-phosphate, another GCKR ligand. Regulation by GCKR makes therefore that glucokinase in intact liver cells has a lower affinity for glucose than the purified enzyme, and that low concentrations of fructose stimulate glucose utilization by the liver. Interestingly, a sequence variant that is commonly found in the human population alters the affinity of GCKR for fructose 6-phosphate and is reproducibly associated with differences in triglyceride and fasting plasma glucose, indicating the importance of GCKR in blood glucose and lipid control.

GCKR also appears to control the subcellular localization of glucokinase: this enzyme is predominantly in the nucleus at low concentration of glucose and in the absence of fructose, but moves to the cytosol when the glucose concentration increases or if fructose is added. The physiological meaning of glucokinase translocation is not known, but it may be to protect glucokinase against degradation by cellular proteases. This would be consistent with the finding that mice devoid of GCKR have lower amounts (and total activities) of glucokinase than control mice. A surprising feature of GCKR is that it

evolved from a prokaryotic enzyme involved in peptidoglycan recycling.

Role of Glucokinase in β -Cells

The low affinity that this enzyme displays for glucose (half-saturation is observed at 8 mM with the human enzyme), the sigmoidal saturation curve, and the lack of inhibition by physiological concentrations of glucose 6-phosphate make this enzyme well suited to respond to changes in glucose concentration and to act thereby as a glucose sensor. This role is well established in the case of the insulin-secreting cells (β -cells) of pancreatic islets. Glucose appears to be one of the main fuels for β -cells. Raising the glycolytic flux (e.g., by raising the glucose concentration) leads to an increase in the cytosolic [ATP]/[ADP] ratio, which in turn results in closure of a nucleotide-sensitive K^+ channel. The ensuing depolarization of the plasma membrane causes an increase in the cytosolic Ca^{2+} concentration, which triggers insulin secretion. Metabolic analyses indicate that glucokinase, not glucose transport or a step beyond glucose phosphorylation, plays a major role in the control of this system. Accordingly, a form of diabetes known as maturity-onset diabetes of the youth type II is caused by glucokinase mutations resulting in decreased enzymatic activity. The disease is dominantly inherited, which means that a mutation in one copy of the gene (resulting at most in a 50% decrease of glucokinase activity) is sufficient to perturb the glucose-sensing apparatus of the endocrine pancreas. Conversely, glucokinase mutations that increase the activity (mostly by increasing the affinity for glucose) result in familial hypoglycemia.

Glossary

Diarylpyrimidine (DAPY) A class of compounds that are potent non-nucleoside inhibitors; etravirine (TMC125) and rilpivirine (TMC278) are DAPY non-nucleoside RT inhibitors (NNRTIs).

Excision Related to the inverse of the polymerization reaction. Reverse transcriptase (RT) uses excision to remove a nucleoside RT inhibitor (NRTI) from the DNA primer terminus.

Non-nucleoside RT inhibitors (NNRTIs) Inhibitors that bind in a hydrophobic pocket near the polymerase active site and block DNA polymerization. Nevirapine, delavirdine, efavirenz, and etravirine are four clinically approved NNRTI drugs for treating human immunodeficiency virus 1 (HIV-1) infection.

Nucleoside RT inhibitors (NRTIs) Analogs of normal nucleosides, which lack a 3'-OH and act as terminators of DNA elongation. AZT (zidovudine) and 3TC (lamivudine) are among the approved NRTI drugs for treatment of HIV-infected patients.

Resistance mutation A change in the amino acid sequence that reduces the susceptibility of the enzyme to an inhibitor.

Reverse transcriptase (RT) A viral enzyme that converts single-stranded genomic RNA into double-stranded DNA.

Thymidine analog mutations (TAMs) A set of RT mutations, also known as AZTr, which facilitate excision to cause NRTI resistance.

Introduction

Human immunodeficiency virus 1 (HIV-1) reverse transcriptase (RT) is a heterodimer consisting of p66 (66 kDa) and p51 (51 kDa) subunits. Both subunits share a common N-terminal domain; p51 lacks the C-terminal RNase H domain present in p66. The p66 subunit of RT has a structure that has been compared to a right hand, having fingers, palm, thumb, and connection subdomains (**Figure 1**). While both the subunits contain the same subdomains, the arrangement of the subdomains is different in p66 and p51. The p51 subunit is not directly involved in DNA polymerization; however, it plays a structural role and forms part of the nucleic-acid-binding cleft that extends from the polymerase active site to the RNase H active site in p66. Non-nucleoside RT inhibitors (NNRTIs) bind to a hydrophobic pocket near the RT polymerase active site and act as allosteric inhibitors that block the chemical step of DNA polymerization. Over the past 20 years, significant progress has been made in understanding the structure and functions of RT. The functional states of RT that have been captured in structural studies can be broadly categorized into: (1) apo HIV-1/HIV-2 RT (in the absence of any bound substrate or inhibitor); (2) HIV-1 RT in complexes with NNRTIs; (3) RT–nucleic acid (double-stranded DNA (dsDNA) or RNA:DNA) binary complexes (with and without the Fab of a monoclonal antibody); (4) RT–nucleic acid–nucleoside triphosphate ternary complexes; (5) RT–nucleic acid–excision product (AZTppppA) complexes; and (6) RT–RNase H inhibitor (RNHI) complexes. Here, we discuss how these structures that have helped elucidate the enzymatic functions of RT, the molecular basis of drug resistance, and aided drug design.

Functional Implications of RT Structures

Comparison of the structures of RT–nucleic acid complexes with apo RT reveals that the thumb of p66 folds down onto the nucleic-acid-binding cleft in apo RT, and binding of a nucleic acid substrate causes the thumb to move out of the cleft to form a clamp that holds the nucleic acid (dsDNA/RNA:DNA). The NNRTI-binding site is in the palm subdomain of p66 near the base of the thumb; the bound NNRTI locks the p66 thumb in an upright position even in the absence of nucleic acid.

The structure of the RT–dsDNA complex revealed details of nucleic acid recognition including the template grip and the primer grip. The polymerase and RNase H active sites, defined by the catalytic carboxylates (Asp110, Asp185, and Asp186 for the polymerase and Asp443, Glu478, Asp498, and Asp549 for the RNase H active sites), both of which are Mg^{2+} dependent, are responsible for the nucleotidyltransferase that polymerizes DNA and the endonuclease that degrades the RNA strand after the complementary DNA strand has been synthesized. The two active sites are separated by 17 DNA base pairs; the nucleic acid substrate is bent at the region that interacts with p66 thumb. The structure of RT complexed with an RNA:DNA duplex led to the identification of the RNase H primer grip, a set of amino acids that interact with the DNA primer strand and help to determine the specificity of RNase H cleavage. The structure of the RT–RNA:DNA complex was determined using an RNase H-resistant RNA, known as the polypurine tract (ppt). During viral replication, the ppt is not cleaved by RNase H and the ppt serves as a primer for the synthesis of the second DNA strand. The RNase H cleavage specificity is presumably

Figure 1 Structure and function of HIV-1 RT. (a) A cartoon representation of HIV-1 reverse transcriptase (RT). The subdomains in the p66 subunit are color-coded: fingers (blue), palm (red), thumb (green), connection (yellow), and the RNase H domain is orange; the p51 subunit is gray. The RNase H active site is shown in red, the site for binding incoming dNTP substrates is gold, and the site for binding NNRTIs is blue. The double-stranded (ds) DNA is shown as a double-helical ribbon with the template (brown) and the primer (purple), extending from the polymerase active site/dNTP-binding site to the RNase H active site. (b) A nucleotide triphosphate (or analog) binds RT and is incorporated at the 3'-end of the DNA primer strand releasing pyrophosphate; the drawing shows the incorporation of AZT-MP.

controlled by the width of the minor groove and the trajectory of the RNA:DNA duplex.

To obtain a structure of a ternary complex of RT with dsDNA and deoxyribose-nucleotidetriphosphate (dNTP), the groups of Stephen Harrison and Gregory Verdine developed a technique in which a disulfide bond was used to covalently link dsDNA to the protein at position 258 of the p66 thumb. Use of a dideoxy-nucleotide at the 3'-end of the primer prevented the incorporation of an incoming dNTP, trapping RT and the substrates in a state preceding DNA-dependent DNA polymerization. In this structure, a portion of the p66 fingers folds down to form part of the dNTP-binding site; the $\beta 3$ – $\beta 4$ loop of the fingers plays a critical role in dNTP binding. An analogous movement occurs in many other DNA polymerases (such as bacterial DNA polymerase I and murine leukemia virus RT, T7 RNA polymerase, and in the RNA-dependent RNA polymerases of poliovirus, foot-and-mouth disease virus, hepatitis C virus, rabbit hemorrhagic disease virus, reovirus, and bacteriophage $\phi 6$). The structural and functional characteristics of these enzymes are useful in understanding the general mechanism of nucleic acid polymerization. The RT–DNA cross-linking technique has been subsequently used to obtain crystals of various RT binary and ternary complexes that are important in understanding the mechanisms of nucleoside RT inhibitor (NRTI) drug resistance.

NNRTIs are highly specific inhibitors of HIV-1 RT; most do not inhibit HIV-2 RT. Four NNRTIs (nevirapine, delavirdine, efavirenz, and etravirine) have been approved for treating

HIV-1 infections. The structure of HIV-1 RT in a complex with nevirapine, from Thomas Steitz and co-workers, was the first structure of RT bound to an NNRTI. Since then, a large number of crystal structures of wild-type and drug-resistant RT–NNRTI complexes have been determined independently by several groups including ours and that of David Stammers and David Stuart. Included among the structures are of RT in complex with α -APA, TIBO, delavirdine, efavirenz, HBY 097, HEPT, PETT, TSAO, DATA, and DAPY derivatives. The conformation of RT in all these structures is similar, having an open nucleic-acid-binding cleft; however, there are significant variations in the shape and size of the NNRTI-binding pocket (NNIBP) related to the size and shape of the bound NNRTI.

Analysis of RT–NNRTI structures has helped in understanding the mechanism of RT inhibition by NNRTIs. NNRTIs are noncompetitive inhibitors that do not interfere with the binding of either the nucleic acid or dNTP substrates. No predefined NNIBP exists in the structures of RT that do not contain a bound NNRTI. Opening of the NNIBP involves large torsional displacements of the aromatic side chains of Y181 and Y188 and a rotation of the $\beta 12$ – $\beta 13$ – $\beta 14$ sheet that moves the primer grip away from the polymerase active site. Once bound, an NNRTI restricts the flexibility of the enzyme. This has two important consequences: (1) primer grip restriction that prevents RT from properly positioning the 3'-end of the DNA primer relative to the polymerase active site and (2) catalytic triad distortion, that is, distortion of the

catalytic triad (Asp110, Asp185, and Asp186) that prevents coordination of catalytically relevant metal ions (Mg^{2+}); there are no crystal structures of an RT–NNRTI complex that have a divalent metal ion bound at the polymerase active site.

NRTI Resistance

The most effective strategy for reducing HIV-1 viral load and keeping it at undetectable levels in patients is by using combinations of drugs (this treatment strategy is called highly active antiretroviral therapy, HAART) that usually include one or two RT inhibitors, sometimes two NRTIs. However, because treatment is lifelong, side effects and the emergence of drug-resistant HIV-1 strains are serious concerns. Resistant strains emerge because of the virus' rapid rate of replication and high rate of mutation. Most of the sites where there are mutations that are associated with drug resistance have the potential to influence (directly or indirectly) the binding of the drug or specific functional steps in reverse transcription. In a number of cases, structural studies in combination with biochemical data and clinical results have helped explain the molecular basis of drug resistance.

Even though all NRTIs lack a 3'-OH and are incorporated at the 3'-end of the DNA primer to inhibit DNA polymerization, there are specific NRTI-resistance mutations associated with treatments with different drugs (Figure 2). There are two primary classes of NRTI-drug resistance mechanisms: (1) exclusion – in which the mutation reduces the ability of RT to incorporate the triphosphate form of the NRTI and (2) excision – in which the mutation enhances the ability of RT to remove an incorporated NRTI. M184I/V mutations are exclusion mutations that emerge in patients treated with lamivudine (3TC), a nucleoside analog that contains a β -L-pseudo-ribose-ring. The structure of the RT–DNA–dTTP complex and the structure of the lamivudine-resistant M184I mutant RT–DNA complex have suggested that replacement of methionine at position 184 with a β -branched amino acid residue (V, I, or T) causes resistance to lamivudine and emtricitabine (FTC) by a steric hindrance mechanism, a proposal that is supported by biochemical experiments. Structures of HIV-1 RT were used to create a structural model of hepatitis B virus (HBV) polymerase. This model has been used to interpret the available biochemical and clinical data describing the resistance/susceptibility of HBV polymerase to nucleotide analogs such as 3TC, FTC, and adefovir (PMEA).

Another exclusion mutation, K65R, was originally isolated from patients treated with ddC or ddI, and subsequently emerged as a primary mutation in patients treated with tenofovir (TFV). The ternary structures of K65R RT in complexes with TFV-DP and the corresponding normal nucleotide deoxyadenosine triphosphate (dATP) revealed that the guanidinium stacking of Arg65 with Arg72 forms a molecular platform (Figure 2(b)). The platform enhances the ability of the mutant RT to discriminate NRTI triphosphates from normal triphosphates. There are other exclusion mutations, including L74V and Q151M (which is usually accompanied by secondary mutations).

AZT treatment frequently selects a set of RT mutations (M41L, D67N, K70R, T215F/Y, and K219Q) that confer

Figure 2 NRTI triphosphates and the locations of NRTI-resistance mutation sites. (a) Chemical structures of NRTIs: 3TC-TP (lamivudine triphosphate), TFVDP (tenofovir diphosphate), and AZTppppA – the product of the ATP-mediated excision reaction that removes AZTMP from the end of the primer strand. Both the AZT-TP and ATP moieties are circled. (b) Close-up of the RT active site showing the superposition of a bound AZT-TP (yellow C-atoms) and dATP (green C-atoms), one of the two active site Mg^{2+} ions that was observed in the crystal structures, and the sites of the primary resistance mutation to 3TC (M184V), TFV (K65R), and AZT (T215Y and K70R). The molecular surface of the Arg72 + Arg65 platform is shown in gray mesh and Val184 in magenta mesh. The primary AZTr mutations T215Y base-stacks and K70R has polar interactions with ATP. Reproduced from Das K, Bandwar RP, White KL, et al. (2009) Structural basis for the role of the K65R mutation in HIV-1 reverse transcriptase polymerization, excision antagonism, and tenofovir resistance. *Journal of Biological Chemistry* 284: 35092–35100.

resistance to AZT; these mutations are referred to as AZTr/TAMs (thymidine analog mutations). However, recombinant HIV-1 RT containing these mutations remained susceptible to inhibition by AZTTP in conventional polymerase assays. The molecular mechanism of AZT resistance was solved in part when Michael Parriak and colleagues proposed that RT performs a pyrophosphate-mediated excision of AZTMP after the

drug has been incorporated. Walter Scott and colleagues suggested that the pyrophosphate donor in the *in vivo* excision reaction is adenosine triphosphate (ATP). We used a combination of biochemical analysis and modeling to propose that the primary AZTr mutations enhance the ability of the mutant RT to bind ATP. Our recent crystal structures of wild-type and AZTr RT-ternary complexes with the ATP-mediated AZT-excision product (AZTppppA, Figure 2) revealed the RT-ATP interactions in atomic detail: the ATP part of AZTppppA binds differently to wild type and AZTr RTs. Wild-type RT has weak interactions with the AMP-part in the wild-type RT-dsDNA-AZTppppA structure, whereas the AZTr mutations create a new high-affinity ATP-binding site. In this site, ATP is predominantly held by stacking the adenine base with Tyr215 and hydrogen bonding of the ribose and α -phosphate with Arg70 (Figure 2). RT can use either pyrophosphate (PPi) or ATP as a pyrophosphate donor to excise the AZT-MP from the primer terminus.

If PPi is the substrate, the excision reaction is the exact inverse of polymerization. However, to generate resistance, the mutant RT must develop a mechanism that allows for efficient excision without perturbing polymerization. Using ATP as the excision substrate allows the enzyme to solve this problem. The excision product, AZTppppA, is a better substrate for AZTr RT than AZTTP, which suggests that the excision-product (AZTppppA)-binding site is a potential target for designing excision-resistant RT inhibitors.

There exist complex relationships among the NRTI-resistance mutations; some co-emerge to enhance resistance and some rarely or never co-emerge. The K65R mutation enhances the resistance to 3TC caused by the M184V mutation; however, the K65R, M184V, or K70E mutations reduce excision by AZTr RT. Some, but not all, of these effects are understood; however, knowing which NRTIs select for antagonistic mutations is an important part of planning optimal HAART strategies.

NNRTI Resistance

Structural studies have shown that NNRTI-resistance mutations are located in and around the NNIBP. Commonly observed resistance mutations in NNRTI-treated patients include K103N, Y181C, L100I, Y188L, and G190A (Figure 3(a)); these can be present singly or in combination. The structural data, supported by clinical and biochemical evidence, suggest that the mutations have different resistance mechanisms. The Y181C and Y188L mutations cause decreased NNRTI binding by the loss of aromatic ring interactions with inhibitors, this is a loss-of-contact mechanism; L100I and G190A/S can cause steric hindrance with NNRTIs; and the K103N mutation appears to affect the entry of an NNRTI into the NNIBP. However, the presence of the K103N mutation can also favor the binding of certain NNRTIs such as TMC125-R165335 (etravirine) (intence).

RT Structures in Drug Design

Variations in RT sequence and the emergence of drug-resistant strains present serious challenges for developing potent

anti-AIDS drugs (acquired immune deficiency syndrome, AIDS). New anti-AIDS drugs should be able to overcome the effects of the commonly observed drug-resistance mutations. A structural understanding of the target enzyme, mode of drug action, and effects of drug resistance can aid the design of potent anti-AIDS drugs. Together with Dr. Paul Janssen and colleagues, we used systematic structural and molecular modeling studies of RT-NNRTI complexes to design new NNRTIs that are effective against a broad spectrum of resistant strains. This multidisciplinary approach helped to develop the novel diarylpyrimidine (DAPY) NNRTIs; the DAPY derivative etravirine has been approved to treat AIDS, and another derivative, rilpivirine (TMC278), has shown positive results in phase III clinical trials. These next-generation DAPY NNRTIs have broad efficacy against commonly observed NNRTI-resistant HIV-1 RT strains. In general, more than two mutations are required to cause significant resistance against the DAPY NNRTIs. Torsional flexibility and the compactness of the DAPY backbone enable these compounds to undergo conformational changes (wiggling) and repositioning (jiggling), allowing these compounds to bind successfully to a variety of NNRTI-resistant mutant RTs (Figure 3(b)). Our high-resolution structures of wild-type and two double-mutant RT-TMC278 complexes (Figure 3(a)) showed that TMC278 can wiggle and jiggle in response to pocket mutations, thus maintaining its binding affinity. The elasticity of the binding pocket permits the protein to shrinkwrap itself around the inhibitor, which can help binding of certain inhibitor particularly to drug-resistant mutants; however, the flexibility of the protein makes it quite difficult to accurately model drug-RT interactions. For this reason, high-resolution structures of RT-NNRTI complexes are valuable guides for NNRTI drug design. Strategic flexibility is emerging as a general principle that can be used in designing drugs against other rapidly evolving targets.

Additional Drug Targets in RT

The second enzymatic activity of RT, RNase H, has not yet been targeted by any drugs. Two types of RNase H specific inhibitors (RNHIs) have been described: (1) active-site metal-ion chelators and (2) nonchelators. The development of anti-HIV-1 integrase drugs that are metal-ion chelators suggests that this is a viable approach. The recent crystal structures of metal-ion chelating RNHIs in complexes with RT and with an isolated RNase H domain have defined the inhibitor-protein interactions and the mode of metal chelation at the RNase H active site – an important step toward developing RNHIs as anti-HIV drugs.

RT is a flexible enzyme with multiple subdomains. In addition to the RNase H active site, the p66/p51-subunit interface and hinges at subdomain interfaces are potential sites for new classes of RT inhibitors. Our recently engineered HIV-1 RT crystals consistently reproduce high-resolution RT structures (better than 2-Å resolution), which opens up new opportunities to screen for RT inhibitors that bind at novel sites by using a crystallographic drug-like fragment screening approach.

Crystallographic studies have played a crucial role in characterizing the molecular interactions of drugs with wild-type

Figure 3 Designing NNRTIs to overcome known resistance mutations. (a) The chemical structure and binding of TMC278 to wild-type HIV-1 RT, as obtained by high-resolution (1.8 Å) crystal structure determination; the torsional flexibility of TMC278 is represented by τ -angles (left) and the non-nucleoside inhibitor-binding pocket (NNIBP) residues are labeled (right). (b) A schematic representation showing how a flexible and compact inhibitor can adapt to changes in the binding pocket (NNIBP) caused by mutations. A rigid inhibitor (left panel), which can bind strongly to the wild-type NNIBP, fails to retain its binding affinity to a mutated NNIBP. A flexible inhibitor (right panel) can adapt to changes in the NNIBP by its torsional rearrangements (wiggling) and repositioning (jiggling). (a) Reproduced from Das K, Clark AD, Lewi PJ, et al. (2004) Roles of conformational and positional adaptability in structure-based design of TMC125-R165335 (etravirine) and related non-nucleoside reverse transcriptase inhibitors that are highly potent and effective against wild-type and drug-resistant HIV-1 variants. *Journal of Medicinal Chemistry* 47: 2550–2560, with permission from American Chemical Society.

and drug-resistant HIV-1 RTs. We believe that structural approaches will become increasingly important in understanding existing and emerging multidrug resistance and in using that information to design improved anti-AIDS drugs and to develop new treatment strategies.

Glossary

AIDS Acquired immunodeficiency syndrome, a devastating disease caused by the HIV.

Enveloped virus A virus that has an outer covering consisting of lipid and protein derived from host cells.

Gag polyprotein A 55-kDa protein produced by translation of HIV messenger RNA.

HIV Human immunodeficiency virus.

Myristolation The addition of a fatty acid chain to the amino terminus of a protein, altering the properties of the protein.

Polyprotein A protein that contains several functional elements attached head-to-tail, which must be separated in order to express their function.

Progeny virus New viral particles produced as a result of replication within an infected cell.

Protease An enzyme that cuts other proteins into pieces.

Retrovirus A virus containing RNA as the genetic element and which must be converted into a DNA copy as part of the replicative cycle.

Virus The simplest form of life, a virus depends on host cells in order to reproduce and continue infection.

Human immunodeficiency virus (HIV) protease is a proteolytic enzyme and is part of the protein component of the HIV. HIV protease plays a critical role in the life cycle of the virus and for this reason has become an important target for drug development in the battle against HIV infection. HIV protease is a member of the aspartic protease family of proteolytic enzymes and discoveries in the general field have provided clues to effective drug design. Subsequently, HIV protease has become one of the most thoroughly studied proteins and most likely has been studied by structural analysis more than any other protein.

Human Immunodeficiency Virus

HIV is an enveloped virus with ribose nucleic acid (RNA) as the molecule used for storage of genetic information. HIV is a retrovirus, which means that the RNA is converted into a deoxyribose nucleic acid (DNA) copy that becomes integrated into the genomic DNA of a host cell. The genomic DNA is transcribed into RNA by the normal cellular machinery and this RNA is used as both messenger RNA for production of proteins by cellular ribosomes and as daughter RNA for assembly into new viral particles. HIV infects cells of the human immune system, leading to death of the cell and, thus, depletion of the immune constituents of the bloodstream with a consequent fall in immune function. Hence, the name of the disease caused by HIV is acquired immunodeficiency syndrome (AIDS). This disease is a scourge upon humankind and, as of early 2010, has killed more than 30 million people worldwide and infected as many as 40 million more.

Proteins of HIV

Gag Proteins

Translation of the gag/pol messenger RNA of HIV leads to the production of two proteins: Gag and Gag/Pol. The Gag polyprotein has a molecular weight of ~55 kDa and is called a polyprotein because it contains several proteins connected head-to-tail. The Gag–Pol polyprotein is produced about 5% of the time when the ribosome reaches a stop codon and slips

back one nucleotide to read in a different frame, thus passing through the stop codon. Three of the proteins of the Gag and Gag–Pol polyprotein (Figure 1) are important constituents of the new viral particles: (1) matrix, or MA, a 17-kDa protein that forms a spherical shell around other proteins, thus providing one level of packaging for the viral particle; (2) capsid, or CA, a 24-kDa protein that forms a conical structure within the matrix shell and contains the daughter RNA, providing a second layer of protection; and (3) nucleocapsid, or NC, a 7-kDa protein that binds to the RNA to provide a third level of packaging. When the new viral particle buds off from an infected cell, it takes some of the cell envelope along with it to complete the packaging of the new virion.

Pol Proteins

The *Pol* gene, which is the second part of the Gag/Pol fusion protein, codes for a polyprotein containing three enzymatic functions: (1) reverse transcriptase (RT), which copies the viral RNA into DNA; (2) protease (PR), which acts to cleave the Gag and Gag/Pol proteins into their separate pieces; and (3) integrase (IN), which catalyzes the insertion of the DNA copy of the viral genetic information into the host cell genome. In addition, several regulatory proteins are produced, including *vif*, *rev*, and *tat*.

Structure of HIV Protease

HIV protease begins as a component of the Gag/Pol fusion polyprotein. As a single molecule, the Gag/Pol-embedded protease is inactive, because dimer formation is required to create the active site and catalytic machinery. Understanding the structure of the Gag–Pol fusion protein is an important objective of current research.

Gag/Pol Polyprotein and Viral Assembly

Following ribosomal synthesis, Gag/Pol fusion proteins become myristolated and assemble on the inner surface of the cell membrane. This concentration of the protein leads to dimerization at

Figure 1 Diagram illustrating the arrangement of the Gag–Pol polyprotein. The letters above the boxes indicate the cleavage sites within the Gag–Pol polyprotein. The codes below the boxes indicate the designations for the protein products of the cleavages.

several points along the polyprotein, including the HIV protease. The dimerization of two protease components of the polyprotein may be assisted by prior assembly of other regions of the protein, such as the proteins in the Gag portion. The viral particle, or virion, buds off from the cell, taking some of the plasma membrane along. At this point, the virus is immature and noninfectious. Upon a change in conditions, possibly caused by an influx of protons into the virion with concomitant decrease in pH, the protease begins its function of cutting apart Gag and Gag/Pol fusion proteins. Little is known about the structure of the Gag/Pol fusion protein in the immature virion. It has been demonstrated that the cleavage of the viral polyprotein into smaller units proceeds by a series of steps that could be controlled by the organization of the polyprotein or by the selectivity of the protease for the different cleavage site junctions.

Structure of HIV Protease as an Isolated Entity

Once released from attachment to the other components of the viral Gag/Pol polyprotein, or when expressed from the 297 bp gene encoding the sequence, HIV protease can be isolated and crystallized. The three-dimensional structure reveals a molecule with structural similarities to other members of the aspartic protease family, but with some significant differences. The enzyme is a dimer of two identical 99 residue monomers and has a folding pattern that contains all the elements seen in the pepsin-like aspartic proteases, including a deep active site cleft on one side of the molecule (**Figure 2**) with both monomers contributing contact sites for bound substrates or inhibitors. Each monomer provides one aspartic acid residue and the carboxylic acid side chains of each of these come together at the bottom of the active site and bind a water molecule, which completes the catalytic machinery. This machinery catalyzes the attack of the water molecule upon the peptide bond of a bound substrate.

Inhibitor Binding

Due to the desire to create potent and selective inhibitors of the HIV protease, many different laboratories, in pharmaceutical companies, in government institutes, and at universities, have studied complexes of HIV protease with small molecule inhibitors. In fact, HIV protease was the first case where structural biology provided key insights that were used to design new, effective compounds. To date, the Food and Drug Administration (FDA) has approved 11 drugs for use in humans and these have had an enormous impact on therapy of AIDS patients, especially when used in combination with inhibitors of the viral proteins RT and IN or an inhibitor of viral entry into cells. The approved compounds provide a longer life span and an improved quality of life. However, problems with the development of resistant variants dampen the success.

Figure 2 Representation of the three-dimensional structure of HIV protease. Two identical domains are shown in orange (left monomer) and blue (right monomer). Each domain contributes one aspartic acid residue to the catalytic machinery at the bottom of the active site cleft. These are shown in space-fill representation near the center of the figure. A bound inhibitor is shown above the two aspartic acids and directly in the middle of the active site cleft. Above the inhibitor, one can see the two prominent β -hairpin flaps, one from each monomer. The flaps cover the inhibitor in the bound state depicted here.

Mode of Inhibitor Binding

Inhibitors bind within the active site cavity of HIV protease, similar to what has been shown for binding of inhibitors against other members of the aspartic protease family. The compounds are arranged in an extended conformation (**Figure 3**) with hydrogen bonding to backbone atoms of the protease and with interactions between groups of the inhibitor and hydrophobic regions of the active site cleft. These interactions provide the specificity and potency of binding necessary to have a compound that will not cause harm to the aspartic proteases of the human host. The FDA-approved drugs all meet these criteria; however, some have side effects that are not completely understood at this time.

Development of Resistant HIV Protease Variants

As a retrovirus, replication of the virus begins with the creation of a DNA copy of the viral RNA genome. The enzyme that performs this reaction, HIV RT, is coded for by the virus and is present in the infectious virion particle. The process does not take place until the virion enters a new cell and the four different barriers protecting the viral RNA are stripped off. HIV RT makes errors while copying the viral genetic information and, unlike DNA polymerases of human cells, HIV RT does not have a proofreading function. This results in nucleotide changes during replication, so that the progeny virus will contain variations on the sequence of the infecting virus. On an

Figure 3 Close-up view of a bound inhibitor (shown in capped-sticks representation at the center of the picture) within the active site cleft of HIV protease. The two catalytic aspartic acids are seen just below the inhibitor. Several amino acids of the HIV protease are shown around the inhibitor. Each monomer contributes several amino acids that make hydrophobic interactions with the bound inhibitor. This view shows a drug-resistant form of protease, with Val32Ile, Val82Ala, and Ile84Val mutations shown in this view.

average, one nucleotide out of the ~9000 nucleotide genome of the virus is altered in each round of replication of virus. As replication takes ~2 days, the number of mutations that can arise over a 6-month period is quite large. Some of these nucleotide alterations will not change the amino acid (silent mutations), but some will. What will be the properties of the new viral protein? In some cases, the progeny virus will be defective and noninfectious, as function could be affected by the mutations. In other cases, the new virus will have favorable properties. This is how drug-resistant variants arise during therapy, especially if the patient does not follow the drug regimen prescribed. Virus that is sensitive to the drug will be killed off, but virus that has properties that include decreased sensitivity to the effects of the antiviral drugs will survive and multiply.

The Spectrum of Drug-Resistant Variants

Out of the 99 amino acid HIV PR, as many as half of the amino acids can change without losing all catalytic activity. In many cases, the efficiency of the enzyme is reduced, but as long as a threshold of activity is maintained (believed to be 10% of starting level), the virus can survive and continue to replicate. Some of the mutations that occur are within the active site cleft and this can change the binding of inhibitors to reduce the effectiveness of antiviral therapy. Discovering new drugs that do not lead to the development of resistance remains a major research objective in antiviral therapy. On the other hand, knowledge of the genetic drift of the virus population into sequences that are resistant to a certain therapeutic regimen can predict when the patient could be switched to another set of antiviral drugs.

Structure of HIV PR Variants

In addition to studies of the structure of HIV protease from laboratory strains of the virus, with the discovery of drug-resistant forms of the virus, it became important to discover how the amino acid substitutions, coded for by the altered forms of the viral genetic information, altered the activity of the protein. Thus, considerable effort has been expended to study the structure of drug-resistant forms of HIV protease. In general, it can be stated that changes in the enzyme structure are small, with obvious changes in the size of an amino acid that interacts with a bound inhibitor in the wild-type enzyme, leading to an obvious hole or protrusion, depending on the direction of the change. Even subtler are changes that occur when amino acids outside of the active site cleft occur, leading to an enhancement of resistance in some cases. A picture is emerging from studies of variant forms of HIV protease that the enzyme is very plastic or malleable, meaning that changes at any single position can be transmitted throughout the enzyme to have an impact on binding within the active site cleft and enzymatic function.

HIV PR as a Model System for Analysis of Protein Structure/Function

The classical history of protein biochemistry has involved studies of a few key proteins: the oxygen-binding proteins, hemoglobin and myoglobin, the proteolytic enzymes trypsin and chymotrypsin, and the nucleic acid degrading enzymes, ribonuclease and staphylococcal nuclease. In the 1990s, HIV protease became a new classical protein that proved to be amenable to detailed analysis. The protein is relatively easy to produce by recombinant means and purify, it has a robust activity and can be analyzed by several different methods, and variants can be created by current methods of molecular biology. Consequently, the HIV protease has been studied by nearly every method of analysis available to the protein chemist. Due to its small size, computational approaches have been applied and HIV protease has become an excellent system for theoretical studies of protein structure/function.

Homologous Recombination in Meiosis

N M Hollingsworth, Stony Brook University, Stony Brook, NY, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Crossover homeostasis The maintenance of a certain number of crossovers (COs) at the expense of non-crossovers (NCOs).

Holliday junction A mobile junction between four strands of DNA.

Homologs Chromosomes with highly similar, but not necessarily identical, DNA sequences.

Hot spot Region on a chromosome that is preferentially cleaved by Spo11.

Interference A CO in one region decreases the probability of a second CO in an adjacent region.

Recombination Includes both crossing over, which is the reciprocal exchange of segments of DNA between homologous chromosomes, and gene conversion, the process by which the sequence of one allele is changed to the sequence of the other allele in the cell.

Sister chromatids Two identical copies of a chromosome created by DNA replication.

Synapsis The physical association of homologous chromosomes during meiosis by the formation of the synaptonemal complex.

Meiosis

Sexually reproducing organisms face a daunting challenge: for the chromosome number of the species to remain constant, the gametes (germ cells) used for reproduction must contain only half the number of chromosomes as the diploid parent. This reduction in chromosome number is achieved by a specialized cell division, meiosis, in which two rounds of chromosome segregation follow a single round of chromosome duplication. DNA replication produces pairs of sister chromatids held together by multi-subunit protein complexes called cohesins (Figure 1, 1). Reciprocal exchange of DNA specifically between nonsister chromatids, in combination with sister chromatid cohesion, physically connects homologous chromosomes, enabling them to orient properly at metaphase of the first meiotic division (meiosis I) (Figure 1, 2). Anaphase of meiosis I is triggered by the removal of cohesins specifically from chromosome arms, allowing homologous pairs of sister chromatids to segregate to opposite poles (Figure 1, 3). At anaphase of the second meiotic division (meiosis II), centromere cohesion is eliminated and sister chromatids segregate to opposite poles, similar to mitosis (Figure 1, 4). The fate of the four haploid products varies in different organisms. In mammals, for example, only one haploid genome from a single meiosis is packaged into an egg, while all four are matured into sperm. In yeast, the four haploid gametes are called spores and they are packaged together into a sac called an ascus (Figure 1, 5).

The Role of Recombination in Meiosis

In addition to independent assortment, crossing over between homologous chromosomes produces new combinations of alleles that provide the grist for evolution. Recombination also plays a critical mechanical role in meiosis by creating

physical connections between homologs that are crucial for proper meiosis I segregation (Figure 1). In the absence of recombination, chromosomes segregate randomly, thereby creating gametes with too few or too many chromosomes. Meiotic recombination is therefore critical to fertility and the production of healthy offspring.

A Molecular Model for Meiotic Recombination

Initiation

The double-strand break repair (DSBR) model for recombination was first proposed in 1983. Since then, many of the molecular intermediates predicted by the DSBR model have been observed experimentally in yeast and the model has gained wide acceptance. The DSBR model proposes that meiotic recombination is initiated by the introduction of a double-strand break (DSB) on one of the four chromatids of a pair of homologs (Figure 2, 1). The formation of DSBs is catalyzed by a meiosis-specific topoisomerase-like protein called Spo11. Spo11 introduces DSBs nonrandomly throughout the genome at places called 'hot spots'. Spo11 cleavage is not sequence dependent, but instead appears to occur primarily in nucleosome-free areas. Yeast cells lacking the Spo11 protein fail to make breaks, undergo no recombination, and exhibit high levels of chromosome missegregation. Meiotic defects resulting from mutation of *SPO11* have also been observed in fruit flies, plants, nematodes and mice, indicating that the mechanism for initiating meiotic recombination is evolutionarily conserved.

Resection

Once a DSB is made, the 5' ends on each side of the break are resected to produce 3' single-stranded (ss) tails (Figure 2, 2). Resection requires a highly conserved protein complex containing Rad50, Xrs2 (Nbs1 in mammals), and Mre11. In yeast,

Figure 1 Chromosome behavior during meiosis. A diploid cell containing a pair of homologous chromosomes (one blue and one red) is shown. Black-filled ovals and circles represent meiosis I and meiosis II centromeres, respectively, to which spindle fibers attach. Arrows connected to centromeres indicate the direction of segregation. (1) Chromosomes replicate to form sister chromatids that are held together by cohesin complexes (indicated by orange bars). (2) Reciprocal recombination, or crossing over, connects homologous chromosomes, enabling their proper alignment at metaphase of meiosis I. Note that sister centromeres function as a single unit. (3) At anaphase I, arm cohesion is removed, and homologous pairs of sister chromatids segregate to opposite poles. (4) At anaphase II, loss of centromere cohesion allows sister chromatids to segregate to opposite poles, similar to mitosis. (5) Four haploid products are packaged into gametes. In yeast, these gametes are called spores.

the absence of any one of these genes prevents DSB formation. However, specific mutant versions of the genes encode proteins that make DSBs, but the breaks remain unprocessed because Spo11 remains covalently bound to the 5' ends of the break. Therefore, DSB formation and 5' end processing are coupled together by these proteins. Resection is initiated when Spo11 is removed by cleavage of the ssDNA on either side of the break, releasing Spo11 covalently attached to a short oligonucleotide.

Invasion

There are two potential sources of homology that can be used as templates for repair of DSBs, sister chromatids and the nonsister chromatids of the homologous chromosomes. Strand invasion is the step at which this decision is made. Although repair occurs preferentially between sister chromatids in mitotically dividing cells, in meiosis this bias is shifted so that interhomolog recombination is favored (Figure 2, 3 and 2–4). This bias is important, as intersister recombination events do not facilitate meiosis I chromosome segregation.

In yeast and mammals, strand invasion is mediated by two recombinases, Rad51 and Dmc1, both highly conserved proteins that are members of the RecA family of strand transferases. Rad51 is the primary recombinase in mitotically dividing cells, whereas Dmc1 is meiosis specific. The proteins form filaments on the ss ends of DSBs and, in conjunction with other proteins, denature homologous duplexes, displacing strands of like polarity to form displacement or D-loops (Figure 2, 3 and 2–4).

Double Holliday Junction Formation and Resolution

After strand invasion, DNA synthesis extends the invading strand, thereby increasing the size of the D-loop until the displaced single strand can complementary base pair with the 3' tail on the other side of the break (Figure 2, 5). A recombination intermediate containing two cross-shaped structures called 'Holliday junctions' (HJs) is then created. To separate the two recombining chromatids from each other, each HJ must be resolved by nicking the two strands of like polarity, followed by religation. To generate a crossover (CO), the two

HJs must be resolved in opposite directions by nicking one pair of strands in one junction and the complementary pair of strands in the second junction (Figure 2, 6).

Crossovers versus Non-Crossovers

Originally, the DSBR model proposed that double HJs could be resolved to yield either CO chromosomes (different strands are cut and ligated in the two different junctions so that the parts of each chromatid distal to the crossover are exchanged) or non-crossover (NCO) chromosomes (the same strands are cut and ligated in the two different HJs so that the arms of the two chromatids are not exchanged) and that this could occur with equal frequency. Subsequent studies have shown, however, that DSBs processed to form double HJs are resolved solely as COs. Instead, NCO chromosomes are proposed to occur by a mechanism called synthesis-dependent strand annealing or SDSA. SDSA results when the extended invading strand is displaced from the D-loop and anneals to the single-stranded end from the other side of the break (Figure 2, 7 and 8).

Studies in yeast have shown that there are approximately 160 DSBs in each meiosis, ~90 of which are processed into COs, ~20 are processed into NCOs, with the remaining presumably repaired using sister chromatids. The relationship between COs and NCOs exhibits 'crossover homeostasis' in that reducing the number of breaks reduces NCOs to a greater extent than COs. This suggests that the cell can preferentially channel breaks into the CO pathway to ensure that homologous chromosomes are physically connected. How the CO/NCO decision is made is not yet understood.

Gene Conversion

Mendel's first law states "alleles segregate equally into gametes." Therefore, when a diploid that contains two different alleles of a gene (+/-) is put through meiosis, half of the gametes should contain the '+' allele and half should contain the '-' allele (indicated by 2⁺:2⁻). The ability in fungi to analyze all four products from a single meiosis (called spores)

Figure 2 Double-strand break repair by meiotic recombination. The DNA duplexes of two homologous chromosomes (one blue and one red) are drawn after DNA replication has produced sister chromatids. The 3' ends of the DNA strands are indicated by circles. (1) Recombination is initiated after DNA replication by the introduction of a DSB on one of the four chromatids by Spo11. (2) The 5' ends of the breaks are resected by Mre11/Xrs2 (Nbs1)/Rad50 to generate 3' single-stranded tails. These tails are coated with the meiosis-specific recombinases Dmc1 and/or Rad51 and the resulting protein/DNA filaments mediate strand invasion of either sister chromatids (3) or the nonsister chromatids of homologous chromosomes (4) to produce D-loops. The size of the arrows indicates a bias for interhomolog recombination at the strand invasion step. Strand invasion of the homolog can result in either CO or NCO chromosomes. For COs, the invading 3' end is extended by DNA replication (indicated by dashed lines), thereby increasing the size of the D-loop (5). Eventually, the D-loop is large enough that the second end of the DSB can be captured by annealing to the displaced single strand of the D-loop, forming two Holliday junctions. Resolution of the two Holliday junctions in opposite directions (indicated by carats) results in two CO chromatids (6). NCOs are created by synthesis-dependent strand annealing (SDSA). The invading DNA is extended (7) but is then removed from the D-loop and the newly synthesized region of DNA anneals with the 3' tail on the other side of the break (8). This end then acts as a primer for DNA synthesis to fill in the gap. Both CO and NCO pathways produce heteroduplex DNA (indicated by black boxes). Correction of mismatches contained in the heteroduplex DNA may result in gene conversion. Although not shown, Holliday junction formation and resolution as well as SDSA can occur between sister chromatids also.

led to the discovery that a small percentage of the time Mendel's first law was broken. In these cases, meiosis produces spores in a ratio of $3^+:1^-$ or $1^+:3^-$ by a process called 'gene conversion'.

Gene conversion changes the sequence of one allele precisely to the sequence of the other allele in the cell. This transfer of sequence information can occur due to the formation of heteroduplex DNA during recombination. Heteroduplex DNA results when a strand of DNA from one homolog complementary base pairs with a strand of DNA from the other homolog. According to the DSBR model, there are two times when heteroduplex is initiated – after strand invasion and after the displaced single strand of DNA in the D-loop anneals to the 3' end on the other side of the break (Figure 2, 6). Because the HJs can branch-migrate along the chromosome, heteroduplex

DNA can be formed some distance from the DSBs. Heteroduplex may also be generated by SDSA (Figure 2, 8). Because the DNA sequences of homologous chromosomes, while highly similar, are not necessarily identical, base-pair mismatches can occur in heteroduplex DNA. These mismatches are then corrected by a highly conserved mismatch repair machinery. A mismatch can be corrected so that the original base pair is restored, thereby producing $2^+:2^-$ spores or it can be corrected so that the sequence of one allele is changed to the sequence of the other allele ($3^+:1^-$ or $1^+:3^-$). Gene conversion has been observed on both CO and NCO chromosomes, consistent with the formation of heteroduplex prior to double HJ resolution or SDSA. Gene conversion has been proposed to play an important role in maintaining the sequence homogeneity of multi-gene families.

The Meiotic Recombination Checkpoint

The introduction of DSBs into chromosomes by Spo11 puts the cell in grave peril. Proceeding ahead through meiosis I with unrepaired DSBs would be fatal, as pieces of broken chromosomes would become irrevocably separated from each other. Once recombination is initiated, therefore, the process is carefully monitored such that meiosis I occurs only after recombination is complete. This surveillance process has been called the 'meiotic recombination checkpoint' or the 'pachytene checkpoint'. For example, budding yeast lacking *DMC1* arrest prior to meiosis I. Examination of the DNA indicates that DSBs are made and resected, but because there is no Dmc1 to promote strand invasion into the homolog, recombination cannot proceed and the meiotic recombination checkpoint is triggered. The cells remain arrested, waiting for the break to be repaired. The meiotic recombination checkpoint also functions in mammals with mutants such as *dmc1Δ* triggering apoptosis in the germ cells of mice. Interestingly, this checkpoint appears to be more robust in males than in females.

Genetic Interference

It is crucial that each pair of homologs receives at least one CO to prevent missegregation at meiosis I. Because in many organisms there is a finite number of COs in each meiosis, COs are distributed so that large chromosomes do not sustain a disproportionate number of COs at the expense of small chromosomes. This distribution is accomplished by a phenomenon known as 'genetic interference'. Interference was first observed at the beginning of the twentieth century when fruit fly geneticists were mapping genes on the same chromosomes. These geneticists found that the presence of a CO in one interval decreases the chance that a second CO occurs nearby. Mutation of genes required for interference in budding yeast increases meiosis I missegregation, especially of small chromosomes. Interference is calculated as $1 - cc$, where cc stands for the 'coefficient of coincidence'. The coefficient of coincidence is the ratio of observed double COs to expected double COs based on the assumption that the two COs occur independently. The strength of interference varies in different parts of the genome, as well as between organisms. COs in nematodes, for example, exhibit interference values close to 1, while fission yeast cells exhibit no interference. Most organisms, such as yeast, fruit flies, and mammals, fall between these two extremes. Despite intense research, the mechanism by which the cell distributes COs through interference remains obscure.

Two Pathways of Crossing Over

Two different classes of interhomolog COs have been observed in budding yeast, plants, and mammals. The majority pathway is mediated by the meiosis-specific MutS homolog pair, Msh4 and Msh5, and these COs exhibit interference. A second, interference-independent set of COs is mediated by a structure-specific endonuclease, Mus81/Mms4 (also known as Eme1).

The Mus81/Mms4 complex has HJ resolution activity *in vitro*, but is not used for resolving HJs in the Msh4/Msh5-dependent COs. Examination of these CO pathways in different organisms has revealed interesting evolutionary divergence. The genome of the nematode, *Caenorhabditis elegans*, is missing *MUS81/MMS4*, and disruption of the *MSH4/MSH5* pathway eliminates all COs. As expected, these COs exhibit very strong interference. By contrast, the genome of the fission yeast, *Schizosaccharomyces pombe*, lacks *MSH4/MSH5*. COs exhibit no interference and are dependent on *MUS81/EME1* (the fission yeast name for *MMS4*). Although it appears that Mus81/Eme1 acts as a Holliday resolvase in fission yeast, the resolvase used for the Msh4/Msh5 pathway remains to be found.

The Synaptonemal Complex

A unique feature of meiosis is the physical association of homologous chromosomes by a meiosis-specific structure called the synaptonemal complex (SC) that is formed by a process called 'synapsis' (Figure 3). After DNA replication, sister chromatids condense along protein cores called 'axial elements' (AEs) that are comprised, at least in part, of meiosis-specific proteins. AEs from homologous chromosomes then become glued together by insertion of the central region to form SCs. In the context of the SC, AEs are referred to as lateral elements. Associated with SCs are densely staining bodies called 'recombination nodules' (RNs). RNs are thought to contain the proteins that mediate recombination. The relationship between the SC and meiotic recombination varies depending upon the organism. In nematodes and fruit flies, SC formation is independent of recombination, whereas in yeast and mammals, recombination is a prerequisite for SC formation. The absence of AEs greatly decreases the frequency of both gene conversion and crossing over between homologous chromosomes, demonstrating that there is an important connection between meiotic chromosome structure and recombination. Furthermore, studies in yeast and nematodes indicate that meiosis-specific components of axial elements are important for promoting interhomolog recombination by suppressing strand invasion of sister chromatids.

Figure 3 The synaptonemal complex. Synapsis of two homologous chromosomes (one blue and one red) is shown.

Mitotic versus Meiotic Recombination

Meiotic recombination exhibits a number of important differences from mitotic recombination. First, meiotic recombination is several orders of magnitude more frequent. This is presumably due to the programmed induction of meiosis-specific recombination proteins such as Spo11. In mitotically dividing cells, recombination is used to repair lesions in DNA and therefore recombination events occur rarely and are located randomly along the chromosomes. In meiotic cells there are 'hot spots' of recombination – these are places on chromosomes where Spo11 prefers to act. In mitotic cells, recombination occurs most frequently between sister chromatids, which act as a template for DNA repair. By contrast, crossing over in meiotic cells is targeted between homologs. This bias is key because only interhomolog crossovers promote proper segregation at meiosis I. Finally, meiotic recombination occurs between homologous chromosomes that are physically associated by a meiosis-specific structure, the SC.

Glossary

Electron paramagnetic resonance (EPR) A spectroscopic method used to detect and characterize paramagnetic species like transition metal complexes, radicals, or triplet states.

FeGP cofactor An iron guanylylpyridone cofactor which is light- and temperature-sensitive.

Fourier transform infrared spectroscopy (FTIR) A spectroscopic method to detect vibrational frequencies of molecules or complexes from different origins.

H-cluster The active site of [FeFe] hydrogenase containing a binuclear iron site ([FeFe] subcluster) and a [Fe₄S₄] subcluster bridged by the thiolate of cysteine residue.

Introduction

Hydrogenases catalyze the reversible oxidation of dihydrogen in nature according to the following simple reaction:

The cleavage of dihydrogen is strongly endergonic – homolytic in the gas phase by +436 kJ mol⁻¹ and heterolytic in water at 20 °C by about +200 kJ mol⁻¹. Heterolytic cleavage is thus energetically favored. The low acidity of H₂ (pK_a ≈ 35) is strongly increased by binding to a metal center. Abundant transition metals, such as Fe and Ni, are used for this purpose in nature by the hydrogenases, whereas precious metals such as Pt are employed in chemical catalysis. The sustainable production and conversion of hydrogen are highly interesting for future technologies.

Hydrogenases are mainly found in microorganisms such as archaea, bacteria, and also in some eukaryotes. They usually live in anoxic environments such as freshwater ponds, marine sediments, swamps, wetlands, and also in hot springs, hydrothermal vents, and even in the intestinal tracts of ruminants and termites. Most hydrogenases are oxygen-sensitive – but in organisms living in aerobic environments some oxygen-tolerant enzymes have been described; examples are found in the Knallgas bacteria (e.g., of the genus *Ralstonia*) or certain thermophiles (e.g., *Aquifex*). Hydrogenases can be classified according to their redox partner, their location in the cell (soluble or membrane-bound), or their function (catalytic or regulatory/sensory hydrogenases). Structurally hydrogenases are divided into three major groups depending on the metal components of their active sites. These are phylogenetically distinct classes and are known as the [NiFe] (subclass [NiFeSe]), [FeFe], and [Fe] hydrogenases:

1. [NiFe] hydrogenases are composed of two subunits and contain the [NiFe] active center, three iron–sulfur clusters, and a magnesium ion (an iron ion in case of [NiFeSe] hydrogenase).
2. [FeFe] hydrogenases are composed of one or two subunits and they consist of at least one iron–sulfur cluster and a di-iron metal center connected via the thiolate of a cysteine residue (so-called H-cluster).
3. [Fe] hydrogenases harbor a unique iron–guanylylpyridinol cofactor (FeGP).

All hydrogenases possess at least one iron in the active site that carries unusual nonprotein ligands such as CO or CN⁻. Their metal active sites are shown in [Figures 1–3](#). Most of the hydrogenases function bi-directionally in H₂-uptake and H₂-production. [NiFe] hydrogenases are usually more active in H₂ oxidation and [FeFe] hydrogenases in the production of H₂. The catalytic activity is often very high. Some [FeFe] hydrogenases are, for example, extremely active in H₂-generation, each molecule of enzyme can produce up to 10⁴ molecules of H₂ per second at ambient temperature. In view of the prospective applications of hydrogenases in biotechnology, for example, for producing dihydrogen or for employing it as an energy source, the interest in these enzymes and their properties has been constantly growing over the past few years. Since the crystal structures of the hydrogenases and their unusual catalytic active centers have been revealed, many bio-inspired synthetic models have been developed to mimic the function of the hydrogenases.

[NiFe] Hydrogenase

Structure

Single crystals and structural information have so far only been obtained from the catalytic standard [NiFe] and [NiFeSe] hydrogenases from sulfate-reducing bacteria, *Desulfovibrio* species, that are discussed here. These are comprised of two subunits ([Figure 1\(a\)](#)). The small subunit harbors three iron–sulfur clusters (2 [Fe₄S₄] and 1 [Fe₃S₄]) that are active in the electron transfer pathway. An exception is the [NiFeSe] hydrogenase that has three [Fe₄S₄] clusters. These metal centers are located within distances of ~13 Å, optimized for efficient electron transfer. The [Fe₄S₄] cluster most distal from the [NiFe] active site is coordinated by three cysteines and one histidine; the others have only cysteine residues. The heterolytic cleavage of dihydrogen takes place at the [NiFe] active site in the large subunit ([Figure 1\(b\)](#)). The iron is six-coordinated, whereas the nickel is only carrying five ligands. The open coordination site at the Ni is believed to be the active site, where the substrate dihydrogen is attached and inhibitors such as carbon monoxide bind ([Figure 1\(b\)](#)). The iron atom is coordinated to three diatomic nonprotein ligands (1 CO and 2 CN⁻). Furthermore, two thiolates of cysteine residues are bridging the iron and the nickel. In addition, two terminal cysteine residues are

(a) Overall structure: the large and the small subunits are shown (yellow and light blue, respectively) and the [NiFe] active site (green/orange), the Mg ion (light green) active in proton transfer, and the three iron–sulfur centers of the electron transfer chain; the hydrophobic gas-access channel is also indicated. (b) [NiFe] active site with its ligands (see text) and the location of the proximal [Fe₄S₄] cluster. The open coordination site is indicated with an arrow. (c) Scheme detailing the various states involved in the enzyme activation (inactive states), in the catalytic cycle (active states), in the CO-inhibition and in the light sensitivity of the [NiFe] hydrogenase.

bound to the Ni atom. In the case of [NiFeSe] hydrogenase, one of the terminal cysteine residues is replaced by a selenocysteine. The third bridging ligand X between Ni and Fe changes identity during the catalytic cycle (Figure 1(c)). It is an oxygenic species in the oxidized state of the enzyme and a hydride in the reduced state. Spectroscopic techniques such as electron paramagnetic resonance (EPR) have shown that the Ni ion is redox active and varies the valence between Ni³⁺ and Ni²⁺ in the catalytic cycle, whereas the Fe atom remains in the low-spin Fe²⁺ state, which is caused by the strong ligand field.

In the C-terminus of the large subunit, a Mg²⁺ ion is found coordinated to the terminal histidine residue, a leucine residue, an oxygen atom from the peptide-backbone, and three water molecules. In the case of [NiFeSe] hydrogenase, an Fe ion is present at the corresponding position. These metals are proposed to play a role in the proton transfer pathway to and from the active site. Since the [NiFe] active site is buried deeply in the molecule, the substrate dihydrogen has to transfer via

gas-access channels. There are several entrances of the gas-access channels but it is a narrow channel in the vicinity of the active site that selects the small molecules, such as H₂, CO, and O₂.

Catalytic Cycle of [NiFe] Hydrogenase

Based on spectroscopic and electrochemical data a number of intermediates in processes related to hydrogenase function could be identified and characterized. This knowledge is summarized in Figure 1(c), which is divided into the inactive, catalytically active, CO-inhibited, and the light-induced states. Nickel is the redox active metal ion and thus the functional scheme consists of a number of EPR-active and EPR-silent states. The enzyme cycles between formal Ni³⁺ and Ni²⁺ states as indicated (a formal Ni¹⁺ state is only present at cryogenic temperatures under illumination). The iron is not redox active, it is always diamagnetic (low-spin Fe²⁺) coordinated by strong π- and σ-ligands, that is, CO and CN⁻.

Figure 2 (a) Three-dimensional representation of [FeFe] hydrogenase from Cpl (PDB ID 3C8Y) and (b) from *D. desulfuricans* (PDB ID 1HFE) showing the active site (H-cluster) and the [FeS] clusters. In the presence of O_2 , catalytic ability is lost. Two paramagnetic inactive states (Ni^{3+} , $S = 1/2$) of the enzyme (Ni-A and Ni-B) have oxo-based ligands bound to the active site bridging Ni and Fe. The Ni-B (ready) state has a μ -hydroxo bridge; this state is quickly activated, a process that finally leads to a loss of the bridging ligand in the active Ni-SI_a state of the catalytic cycle. The Ni-A state (unready) is slowly activated. It is absent in all oxygen-tolerant [NiFe] hydrogenases. A final conclusion on the bridging ligand has not been made.

One-electron reduction of Ni-B and Ni-A leads to the formation of the EPR-silent (Ni^{2+}) catalytically inactive states Ni-SI_r and Ni-SU, respectively. Ni-SI_r exists in two forms that are in an acid-base equilibrium: the (Ni-SI_r)_I and the more protonated (Ni-SI_r)_{II}. In this process, the μ -hydroxo bridge is protonated (to form water) prior to converting to the active Ni-SI_a state, which lacks the bridge X.

The physiological states related to dihydrogen catalysis are Ni-SI_a, Ni-C, and Ni-R (Figure 1(c)). Ni-SI_a is the most oxidized active intermediate and is EPR-silent (Ni^{2+}). It has an open bridging position and the nickel is thus only four-coordinated. It is suggested that this state attaches the dihydrogen, which is polarized and heterolytically split. The Ni is probably the site of H_2 binding since CO is also attached to this metal and the gas-access channel ends close to the nickel ion (Figure 1(a)). The open bridging position between Ni and Fe has also been discussed as the primary site of dihydrogen attack.

Proton-coupled one-electron reduction leads to the catalytic Ni-C state. In this step, base-assisted heterolytic cleavage of the H_2 molecule takes place, leaving a hydride ligand (H^-) in the bridging position between Ni and Fe, and an electron is released to the proximal $[Fe_4S_4]$ cluster. One of the candidates for the respective base is a terminal cysteine that can then transfer the proton to a nearby glutamic acid. Alternatively, the proton could be taken up by another cysteine residue or even by a water molecule loosely bound to the Fe, as has been proposed in another mechanism.

Proton-coupled one-electron further reduction of Ni-C leads to the EPR-silent state Ni-R. However, Ni-R can also be formed directly from the Ni-SI_a state after its reaction with H_2 if all three clusters are already reduced, without the Ni-C being observed as a detectable intermediate. Ni-R is the most reduced state of the enzyme and can exist in three isoelectronic forms that differ in the protonation degree either of the coordinating cysteine residues or of the substrate ligands (e.g., H_2 and H^-) bound to the active site. All details of the mechanism are not available experimentally, a fact that has led to several mechanistic proposals. An interesting alternative to the above-discussed scheme has been postulated, in which only the Ni-R and Ni-C states are involved in catalysis.

Whereas the fully oxidized states Ni-B and Ni-A are not light sensitive, the Ni-SI_r state upon illumination forms an EPR-silent species denoted as Ni-SL, for which a displacement of the μ -hydroxo ligand has been postulated. Illumination at low temperatures also affects the Ni-C state, which converts to a paramagnetic state termed Ni-L, with a concomitant loss of the hydride bridge in form of a proton. Ni-L is described by a formal Ni^{1+} state. Several Ni-L forms have been reported, which most likely differ with respect to the location of the proton. Light-induced structural changes have also been reported for the Ni-R states.

It has been demonstrated by X-ray crystallography that externally added carbon monoxide binds terminally to the nickel ion and inhibits the enzyme. Two distinct CO-inhibited redox states have been characterized by spectroscopy: a paramagnetic Ni-CO and an EPR-silent Ni-SCO state. Both are light sensitive, leading to photodissociation of the extrinsic CO ligand; Ni-CO converts to the same Ni-L state as Ni-C, while Ni-SCO converts to Ni-SI_a. Only four-coordinated nickel in a low oxidation state, either Ni^{2+} as in Ni-SI_a or Ni^{1+} as in Ni-L, has the affinity to bind carbon monoxide.

[NiFe] hydrogenases have the advantage that they are less oxygen sensitive than [FeFe] hydrogenases, with the O_2 inhibition being often reversible, while there are a few hydrogenases, for example, from Knallgas or hyperthermophilic bacteria, which are even oxygen tolerant. Models for their oxygen tolerance are currently being developed.

[FeFe] Hydrogenase

Structure

[FeFe] hydrogenases are composed of several subunits depending on the organisms. The core structure contains the H-cluster that consists of a bimetallic [FeFe] center, which is connected to an $[Fe_4S_4]$ cluster by a thiolate of a cysteine residue (Figure 2(c)). Most of [FeFe] hydrogenases contain additional $[Fe_4S_4]/[Fe_2S_2]$ clusters, whereas the [FeFe] hydrogenase from green algae contains only the H-cluster and no other iron-sulfur cluster.

The crystal structures of the periplasmic [FeFe] hydrogenase from *Desulfovibrio desulfuricans* and the cytoplasmic [FeFe] hydrogenase from *Clostridium pasteurianum* (CpI), have been determined at atomic resolution (Figures 2(a) and 2(b)). They revealed the unique features of this type of enzyme. CpI comprises only one amino acid chain and possesses an H-cluster, three $[Fe_4S_4]$ and one $[Fe_2S_2]$ cluster. The [FeFe] hydrogenase from *D. desulfuricans* consists of two subunits harboring the H-cluster and two $[Fe_4S_4]$ clusters; the structure of the active site is very similar to CpI.

As found for the active site of [NiFe] hydrogenases, the irons are also coordinated by nonprotein ligands, such as CO and CN^- (Figure 2(c)), which stabilize the iron in low oxidation states (here $Fe^{1+/2+}$). One CO is bridging the two iron ions. The diatomic ligands have been assigned on the basis of the surrounding amino acid residues: the CO ligands are located in a hydrophobic pocket and the CN^- ligands form hydrogen bonds to nearby amino acid residues. This assignment is corroborated by Fourier transform infrared spectroscopy (FTIR) spectroscopy. Furthermore, the two iron ions are bridged by a dithiolate unit. The apical atom was identified as a nitrogen atom by pulse EPR techniques. A hydrophobic gas-access tunnel has been found connecting the molecular surface and the distal iron Fe_d of the H-cluster. This gas-access tunnel is much shorter than that of [NiFe] hydrogenases. Fe_d is proposed as the initial site of dihydrogen conversion. In CpI the $[Fe_4S_4]$ clusters, serving as an electron transfer chain, are located within a distance of approximately 11 Å. The distal $[Fe_4S_4]$ cluster in CpI is coordinated by three cysteine and one histidine residues, as found in the case of [NiFe] hydrogenases. The other $[Fe_4S_4]$ clusters are coordinated by four cysteine residues.

Catalytic Cycle of [FeFe] Hydrogenase

Application of spectroscopic and electrochemical techniques, together with quantum chemical calculations, has led to the proposal of a reaction scheme for [FeFe] hydrogenases (**Figure 2(d)**). The most oxidized state, H_{ox}^{air} , is inactive and probably has an OH^- (or H_2O) ligand bound to the open coordination site at the distal Fe_d in the di-iron subcluster; in this state both irons are low-spin Fe^{2+} . One-electron reduction of the H_{ox}^{air} state leads to the H_{trans} state in which the $[Fe_4S_4]^{2+}$ subcluster is reduced to $[Fe_4S_4]^+$, but both irons of the binuclear [FeFe] subcluster remain Fe^{2+} . As a result of conversion of the H_{trans} state, the enzyme reaches the catalytically active state H_{ox} . This state is EPR-active with an oxidized $[Fe_4S_4]^{2+}$ and a mixed $Fe^{1+}Fe^{2+}$ subcluster ($S=1/2$), in which the terminal OH^-/H_2O ligand at Fe_d is removed. The substrate H_2 can now bind to the active site, that is, at Fe_d . In this process, the dihydrogen bond is polarized and heterolytic splitting occurs, with the nitrogen in the dithiolate bridge acting as a suitable base. In the most reduced state, H_{red} , the bridging CO could break the bond to the proximal Fe_p and move toward the distal Fe_d site, allowing the hydride to occupy the rather stable bridging position between the two iron ions. Alternatively, the hydride could remain bound end-on at the distal iron. In the catalytic cycle, the valence of the $[Fe_4S_4]^{2+}$ subcluster is retained, whereas the [FeFe] subcluster is proposed to change the valence from $Fe^{2+}Fe^{2+}$ to $Fe^{1+}Fe^{1+}$ (**Figure 2(d)**). It is not yet entirely clear if the proton reduction (H_2 production) and H_2 oxidation (uptake reaction) will follow the same mechanism.

The [FeFe] hydrogenase is (reversibly) inhibited by carbon monoxide. The external CO binds to the open coordination site of the distal Fe_d in the H_{ox} state resulting in an EPR-active state, termed $H_{ox}-CO$. The enzyme is very sensitive to molecular oxygen, which restricts its use in biotechnological processes. The oxygen has been proposed to initially bind to the open coordination site (e.g., in H_{ox}) before further reacting and destroying the H-cluster. The mechanism of the oxygen inhibition and destruction of the cluster has not yet been elucidated.

[Fe] Hydrogenase

Structure

[Fe] hydrogenases are found only in methanogenic archaea, which convert carbon dioxide with H_2 to methane in a complex reaction. [Fe] hydrogenases catalyze the reversible reduction of the substrate methenyltetrahydromethanopterin (methenyl- H_4MPT^+) with H_2 to methylene- H_4MPT and a proton by transferring a hydride ion to the *proR* position of the C14a carbon of methylene- H_4MPT . Its structure and catalytic reaction mechanism differ from those of [NiFe] or [FeFe] hydrogenases but it shows the typical reactions of hydrogenase (e.g. H^+/H_2 exchange; para/ortho H_2 conversion).

The crystal structures of [Fe] hydrogenase from *Methanocaldococcus jannaschii* and *Methanopyrus kandleri* have been determined at atomic resolution. Furthermore, the hydrogenase-substrate complex has also been described (PDB ID 3 H65). [Fe] hydrogenase is a homodimeric protein and comprises two peripheral units bound to the central globular unit in a linear manner (**Figure 3(a)**). These subunits form an intertwined

intersubunit helix bundle. Structural change from the open to the closed form occurs when the substrate methenyl- H_4MPT^+ binds to the enzyme. The cleft between the peripheral unit and the central globular unit in the open form has a depth of 13 Å. The enzyme harbors a unique iron-cofactor (iron-guanylylpyridinol, FeGP) and contains no iron-sulfur clusters. The iron is five-coordinated; ligands are a thiolate from a cysteine, two CO molecules, a nitrogen (sp^2) and an acyl-carbon from the pyridinol of the GP (see **Figure 3(b)**). The open coordination position is supposed to be the site of dihydrogen activation.

Catalytic Mechanism of [Fe] Hydrogenase

The catalytic mechanism of [Fe] hydrogenase differs fundamentally from that of the other type of hydrogenases. **Figure 3(c)** shows the proposed reaction scheme. In the first step, the methenyl- H_4MPT^+ substrate binds to the open form and the cleft between the two domains is closed (**Figure 3(c)** I/II). The substrate is probably activated in this process leading to a carbocationic character of the carbon C14a. The dihydrogen molecule binds side-on to the open coordination site of the iron of the activated FeGP complex (**Figure 3(c)** III). The oxidation state of the iron is proposed to be low-spin Fe^{2+} . The hydrogen is heterolytically cleaved by the adjacent C14a carbocation acting as a Lewis acid and the hydride is transferred to the methenyl- H_4MPT^+ (**Figure 3(c)** IV). The proton derived from the heterolytic cleavage of H_2 is accepted by a base (a cysteine thiolate or the pyridinol hydroxylate group) and is expected to exchange quickly with protons of the bulk solvent.

The dinuclear C-Fe arrangement of the [Fe] hydrogenase resembles that of the dinuclear metal centers of the [NiFe] and [FeFe] hydrogenases with respect to arrangement and the presence of a low-spin Fe^{2+} . The only variable is the first cation which can be a nickel, an iron, or even a carbon. This suggests a convergent evolution of the H_2 -activation machinery.

Immunoglobulin (Fc) Receptors

M Hogarth, Burnet Institute, Prahran, VIC, Australia

Published by Elsevier Inc.

Glossary

Autoimmune disease Diseases where the immune system attacks the hosts' tissues and/or organs. Examples include rheumatoid arthritis and systemic lupus erythematosus.

Hypersensitivity Powerful and frequently destructive inflammatory reaction often induced by antibodies in autoimmune diseases.

Leukocyte White blood cell including eosinophil, polymorphonuclear leukocyte or neutrophil, macrophage, monocyte, mast cell, basophil, and lymphocyte.

Phagocyte Cell that actively ingests particles, typically macrophage or neutrophil.

Phagocytosis Process distinct from pinocytosis by which particles are taken into the cell. Unlike pinocytosis, considerable intracellular and membrane reorganization is required for the uptake of the particle.

Pinocytosis Process by which cells sample small amounts of fluid from their surrounding environment. This usually involves internalization of small vesicles formed from the invagination of the cell membrane.

Immunoglobulin Fc receptors (FcRs) are cell surface molecules that bind the Fc portion of immunoglobulin. Receptors have been identified for all immunoglobulin classes and subclasses with the exception of IgD. Note that microbial proteins that can also bind the Fc portion of immunoglobulin are not receptors but should be regarded only as Fc-binding proteins. Such proteins include, for example, staphylococcal protein A.

General Comments

When antibodies contact their specific antigen, they form an immune complex and in the case of most pathogens, many antibodies will coat a single macromolecule or pathogen fragment leading to the formation of multimeric immune complexes. These multimeric, and therefore oligovalent, complexes of antibody and antigen then interact with specific cell surface Fc receptors and this interaction subsequently initiates signaling cascades inside cells.

The affinity of the interaction between the different Ig subclasses and specific Fc receptors varies by as much as 1000-fold, ranging from low micromolar affinity for the so called 'low-affinity' IgG receptors to nanomolar affinity for the high-affinity IgG receptor. Furthermore, the high affinity IgE receptor binds IgE with femtomolar affinity. Such a vast range of affinities has specifically evolved to suit the biological activities of particular receptor types.

The nomenclature of FcRs is, as the name suggests, based on the capacity to bind the Fc portion of a particular class of antibody, for example, IgM, Fcμ; IgG, Fcγ. The letter R designates

a receptor and a Roman numeral designates a particular subtype of FcR, for example, FcγRII. These can be further subclassified by letters a, b, c, etc., for example, FcγRIIIa. Note also that several receptors are also given an alternative designation as part of the cluster of differentiation (CD) system of classifying leukocyte surface molecules; thus, FcγRI is known also as CD64, FcγRII as CD32, FcγRIII as CD16, and FcεRII as CD23.

The vast majority of FcRs are found on leukocytes FcεR and FcαR where they are involved in the regulation of cellular activity by antibody. Most leukocyte FcRs are primarily designed to activate cells and with one notable exception, are multisubunit complexes. However, a discrete and unique class of FcR is able to downregulate leukocyte activity following their binding of immune complexes.

Fc receptors are largely found on leukocytes, which have been the principal subject of most research. However, several other FcRs have been identified, present on epithelial and endothelial cells with specific functions related to transport and recovery of immunoglobulins and are considered separately below.

Leukocyte FcRs

Most leukocyte FcRs are multisubunit complexes requiring a ligand-binding chain noncovalently associated with a signaling chain and in some cases with an additional signal amplifying subunit (Figures 1 and 2). The biochemical and functional characteristics of the most frequently studied FcR of leukocytes are detailed below.

Figure 1 Schematic representation of a typical multisubunit Fc receptor. The typical components of many Fc receptors found on leukocytes. A ligand binding chain, usually a type-1 transmembrane glycoprotein, is noncovalently associated with other subunits: a signaling chain, often the FcR- γ chain, which is a 24-kDa covalent homodimer wherein each monomer contains an ITAM, a specialized tyrosine-containing signaling motif (green annulus). In at least two cases the ligand-binding chain is further associated with a tetra transmembrane signal-amplifying chain.

Figure 2 Schematic representation of leukocyte FcR showing configuration of signaling-competent receptor complexes. FcγRII (not shown). ITAMs are shown as green annulus; the FcγRIIb ITIM as a red crossed circle.

IgE FcRs

The high-affinity IgE receptor FcεRI binds monomeric IgE with an affinity of greater 10^{10} M^{-1} and is found principally on mast cells and basophils and in a modified form on eosinophils and monocytes where it lacks the amplifying beta chain (see below). The binding of IgE to this receptor and the subsequent cross-linking of the bound IgE by antigen induces one of the most potent pharmacological responses in biology. In adverse situations this results in a classic type-I hypersensitivity reaction clinically manifested as allergy, for example, hay fever, penicillin, or food allergies. The FcεRI signaling is mediated via a noncovalent association with a low-molecular-weight transmembrane dimer called 'Fc gamma chain (FcR γ)'. This chain is shared by several other Fc receptors. Unlike the high-affinity IgE receptor, the FcεRII (CD23) binds IgE with a lower affinity (10^7 M^{-1}). This is a type-II membrane glycoprotein with lectin-like activity and is found on many leukocytes including T-cells, B-cells, and monocytes. Its function appears largely to regulate activity of immune responses.

These receptors are biochemically distinct. FcεRI is a transmembrane glycoprotein and is a member of the Ig superfamily with two extra cellular domains, each of which belong to the Ig super family. By contrast, FcεRII is a type-II membrane glycoprotein with lectin-like activity.

IgG Receptors

In humans, there are three main subtypes of leukocyte IgG Fc receptors – FcγRI, FcγRII, and FcγRIII (Figures 2, 3(a), and 3(b)). Splice variants and multiple gene products are known for FcγRII and FcγRIII. (Note that while the mouse and humans share many features of IgG Fc receptors, there are significant differences, i.e., mice do not have orthologs of FcγRIIa, FcγRIIc, or FcγRIIb; humans lack an ortholog of mouse FcγRIV.) The FcγR are widespread and every leukocyte with the exception of $\alpha\beta\text{T}$ lymphocytes expresses one or more of these receptors. The different receptors can be distinguished by amino acid sequence and by the use of specific monoclonal antibodies and by differences in affinities for IgG.

FcγRI (also known as CD64) is the high-affinity receptor for IgG (10^8 M^{-1}) and is restricted largely to monocytes, macrophages, and neutrophils.

FcγRII (CD32) is composed of two major subtypes: FcγRIIa and FcγRIIb, which are separate gene products and are biochemically distinct. The extracellular domains are highly related in sequence but their transmembrane and cytoplasmic tails are distinct, which reflects their distinct signaling activities of activation or inhibition, respectively. Indeed, FcγRIIb is the only inhibitory FcγR. (see below). Both bind monomeric immunoglobulin IgG with very low affinity (one micromolar) evident by the rapid on and off rate; however, since these low-affinity receptors decorate the cell membrane they can effectively, and very avidly, bind oligovalent complexes of antigen and antibody. FcγRIIa is found on virtually every leukocyte including platelets. FcγRIIb, similarly, is found on virtually every leukocyte including B-cells but not platelets. Note that a third form, FcγRIIc, has been described but little is known of its function. Its extracellular domains are closely related to those of the inhibitory receptor FcγRIIb whereas its cytoplasmic domain contains an immunoreceptor tyrosine-based activation motif (ITAM), as does FcγRIIa.

FcγRIII (CD16) also has two subtypes: FcγRIIIa and FcγRIIIb. Both are low-affinity receptors though they bind with IgG with 10-fold higher affinity than the FcγRII low-affinity receptors. FcγRIIIa is found on natural killer cells, macrophages, and some monocytes, whereas FcγRIIIb is found only on neutrophils.

All of these FcRs belong to the Ig super-family. Each has two extracellular Ig-like domains with the exception of FcγRI which has three (Figure 2). Another interesting difference is that while FcγRI, FcγRIIa, and FcγRIIa are transmembrane glycoproteins, FcγRIIb is a glycosylphosphatidylinositol (GPI)-anchored receptor (Figure 2).

IgA and IgM FcRs of Leukocytes

A single receptor specific for IgA has been defined – FcαRI which is found on neutrophils and monocytes (Figure 2). The affinity for IgA is approximately 10^7 M^{-1} , but immune complexes of IgA binding to FcαRI are potent inducers of cell activation. A receptor that is able to bind both IgA and IgM, the FcαR of Fcα μ R, has also been defined though there has been relatively little characterization of this.

Figure 3 FcR structure. Shown are the alpha carbon backbones of selected Fc receptors and ligands. (a) Comparison of the interaction of IgG with Fc γ RIIa or Fc γ RIIIa; from the database: PDB 3RY6; PDB, 1E4K. The receptors' second domain and interdomain region interacts with the lower hinge region and hinge proximal parts of the IgG Fc giving the characteristic 1:1 stoichiometry. (b) Comparison of the two dimeric forms of Fc γ RIIIa (PDB 1FCG) and the second derived from PDB 3RY6. This receptor is unique as it forms a noncovalent homodimer. In the case of the left dimer, binding of IgG is not possible because steric clashes between the dimer and C γ 2 prevent proper interaction of domain 2 with the lower hinge of IgG. However, in the second dimer the binding surfaces are sufficiently separated to allow interaction with an IgG Fc for each receptor in the dimer, that is, one dimer interacts with one or two Fcs. (c) Complex of Fc γ RI and IgA (PDB, 1OW0). Interaction between the tip of the first domain of Fc α RI and the C α 2/C α 3 junction of each Fc chain gives the 2:1 stoichiometry. (d) Structure of FcRn and IgG complex (PDB, 111A). Interaction of the FcRn first domain with amino acids in the junction of C γ 2 and C γ 3 of a single Fc chain. The β 2 microglobulin typically associated with MHC class I molecules is shown associated with FcRn ectodomains. In all figures the polypeptide chains are represented as α -carbon backbones; strands as arrows and α -helices as barrels. The C terminus of each polypeptide chain is shown in red. Constant regions of IgA or IgG are indicated – C α or C γ and the position of the hinge are shown. Orientation of the polypeptides to the membrane is assumed.

Of most recent interest is the identification of an IgM receptor, FcμR, which had historically been very difficult to identify but relatively little biology is known of this receptor.

Sites of Interaction with Ig Ligands

The Ig binding sites of FcγRI, FcγRII, and FcγRIII are located in similar regions in these structurally related but functionally distinct receptors (Figures 3(a) and 3(b)). The identity of the Ig-binding sites of many of the receptors has been extensively investigated and defined by mutagenesis and by X-ray structures. In the case of the IgG receptors FcγRII and FcγRIII – and probably FcγRI – the site is located in the second domain together with sequences at the junction of the first and second domains as seen in the similar crystallographic structures (Figure 3(a)). Interestingly, FcγRIIa can form distinct dimers only one of which is able to interact with IgG (Figures 3(c) and 3(d)). The stoichiometry of FcγR:IgG interaction for all IgG receptors is 1:1 (Figure 3(d)).

The interaction of IgE and the high-affinity IgE receptor FcεRI occurs in the second domain of FcεRI and the stoichiometry is 1:1. Crystallographic studies show the interaction is similar to that of the related FcγR and IgG. In the case of the low-affinity IgE receptor, FcεRII, the head groups of the triple helix interact with IgE also in a 1:1 stoichiometry.

Although distantly related to the FcγR and FcεRI, the IgA receptor, FcαRI, binds IgA to the extreme tip of its first domain which allows it to form a rather unique 2:1 stoichiometry with IgA (Figure 3(d)).

Receptor Binding Sites in Immunoglobulin

FcγRI, FcγRII, and FcγRIII interact with sequences in the lower hinge and adjacent areas of Cγ2 of the IgG Fc (Figure 3(a)). Differences in the nature and extent of these interactions explain the differences in affinity of FcR:Ig interaction. FcεRI interacts with sequence between Cε2 and Cε3, which is distinct from the area of the sites of interaction of FcεRII. The nature of these interactions clearly defines the stoichiometry. FcαRI interacts with the area between Cα2 and Cα3. Currently, there is no information on the interactions of FcαμR and IgA/IgM or for FcμR and IgM.

Signal Transduction Complexes

With the exception of FcεRII, there has been a great deal of investigation of the signal transduction by leukocyte Fc receptors which have become one of the most widely studied groups of receptors. The binding of antibody or immune complexes to these can be a potent inducer of biochemical signals, but FcγRIIa and FcγRIIb have additional unique biochemistry. The structurally related leukocyte receptors – FcγRI, FcγRII, FcγRIIIa, and FcεRI – as well as the more distantly related FcαRI all signal by very similar mechanisms dependent on ITAM which involve the *syk* and *src* family protein tyrosine kinases. To signal, these receptors must form multisubunit

signaling complexes composed minimally of the Fc-binding chain (all of which are the Ig superfamily members), noncovalently associated with a low-molecular-weight hetero- or homodimeric signaling chain – the common FcR-γ chain or in the case of FcγRIIIa in NK cells the CD3-ζ chain (Figures 1 and 2).

The ITAM motif that is necessary for recognition by *syk* and *src* kinases is contained in these associated low-molecular-weight dimers. Cross-linking of the FcR by immune complexes, or by antigen to cell-bound Ig, aggregates the receptors leading to phosphorylation of tyrosine in the ITAMs and the subsequent induction of the signaling cascades. Similar mechanisms of leukocyte activation are well described for the antigen receptors of T- and B-lymphocytes.

FcγRIIa stands out as an exception to the multisubunit paradigm for ITAM-dependant immunoreceptor signaling (Figures 2 and 3(d)). While aggregation of this receptor leads to *syk* and *src* kinase activation, this receptor does not require association with the common FcR-γ chain. Since a noncanonical, the ITAM is contained within its cytoplasmic tail. Indeed, FcγRIIa is one of the few immunoreceptors to have the ITAM motif contained in the ligand-binding chain. This receptor forms either of two unique dimers on the cell surface; one dimer form is incapable of binding IgG (Figure 3(c)). However, a second dimer of receptors is formed with either one or both receptors liganded with IgG (Figure 3(d)). As a result, the cytoplasmic ITAM motifs are juxtaposed thereby forming the necessary dimeric ITAM configuration for signal transduction, equivalent to that of the FcRγ chain that associates with other activating FcR.

FcγRIIb is not an activating Fc receptor; indeed, its role is to inhibit and regulate the activities of other ITAM-containing activating Fc receptors and the antigen receptor of B-cells. The cytoplasmic tail of FcγRIIb contains an immunoreceptor tyrosine inhibitory motif (ITIM) which on co-aggregation with ITAM-containing activating receptors recruits phosphatases which in turn downregulate or eliminate ITAM-dependent signal transduction. Its best-characterized role is its co-engagement with the antigen receptor of B-lymphocytes where it regulates B-cell activation by antigen.

Other Leukocyte FcRs

In recent years, especially with the output of the human and mouse genome projects, new cell surface molecules with FcR-like activity have been described though they are currently poorly characterized. Nonetheless, for the sake of completeness they have been included here. The most advanced characterizations have involved the leukocyte in receptor cluster, which is a large family of cell surface molecules present on leukocytes but most of these do not show immunoglobulin binding activity. Biochemically, these molecules include members with multiple Ig-like domains and with tissue distributions ranging from the highly restricted to the very broad. The precise biochemical nature and biological roles are poorly understood but will no doubt be revealed in time, although from sequence comparisons some members are likely to have ITIM-like inhibitory activity and others ITAM-dependant activation roles.

Nonleukocyte Fc Receptors

Two major Fc receptors have been defined: the poly Ig receptor (poly IgR) and FcRn.

The poly Ig receptor is responsible for the binding and transport of the secretory immunoglobulins – IgA and IgM. It is found on secretory epithelium, notably in the lactating breast, as well as mucosal surfaces. This is a cell surface molecule composed of five domains: the IgA and IgM-binding sites occur in the first two domains which when attached to sIgA or sIgM are cleaved from the receptor and thereby form the so-called ‘secretory component’ associated with secretory IgA and IgM.

FcRn was originally described as a receptor on epithelial and endothelial cells. In humans, its main function is the recycling of immunoglobulins to/from the circulation which ensures the prodigious half-life of IgG. Intact and undenatured IgG which is taken into endothelial cells by pinocytosis is recycled to the circulation following its pH-dependent attachment to FcRn in the acidifying pinocytotic vesicle where it undergoes acid-dependent attachment to FcRn which results in recycling to the endothelial cell surface and release at the neutral pH of the circulation. Recently, it has become apparent that FcRn is expressed on leukocytes where it internalizes IgG including IgG:antigen complexes; such an internalized antigen can then enter antigen-processing pathways of the leukocyte.

FcRn is biochemically distinct from all other leukocyte and nonleukocyte Fc receptors (Figure 3(f)). It is a transmembrane glycoprotein but it is more structurally related to the major histocompatibility molecules (MHC class I) whose principal function is antigen presentation to T-cells. However, it is sufficiently biochemically different from these which makes it unable to be involved directly in presentation.

Biological Role of Leukocyte FcRs

The leukocyte receptors FcεRI, FcεRII, FcγRI, FcγRII, and FcγRIII participate in a range of normal functions most of which is associated with the activation of leukocytes and the modulation of immunity which then leads to specialized functions associated with different cell types, for example, the degranulation of mast cells and the release of inflammatory mediators caused by aggregation of the high-affinity IgE receptor by IgE: antigen complexes. However, for the most part, FcγRI, FcγRII, and FcγRIII appear to be mostly concerned with antibody-dependent activation and modulation of innate and adaptive immunity rather than the historical view that Fc receptors on cells such as macrophages, dendritic cells, and other phagocytes serve the principal role for the phagocytic removal of immune complexes.

It is now clear that these receptors play a far more active and critical role rather than one of simple garbage disposal of immune complexes, a function which, in humans, is largely filled by the complement system and, in particular, CR-1 on erythrocytes.

This capacity to bind immune complexes, though not in itself pathogenic, can in the presence of aberrant immune complexes, such as autoantibody, lead to the potent and continuous stimulation of leukocytes, leading in turn to pathological

inflammation and tissue destruction. This is clearly the case in diseases such as systemic lupus erythematosus, rheumatoid arthritis, and glomerulonephritis, allergies which are associated with major morbidity. Attempts to interfere with the interaction of immune complexes with Fc receptors are now forming the basis of novel approaches to the treatment of those diseases.

Key Events in the Analysis of FcR

The existence of specific receptors for immune complexes was noted in the early 1970s by Metzger and by Basten and their co-workers. The observation by Metzger and Bevan that engagement of these receptors could induce a measurable intracellular biochemical event was an exciting observation of importance, not only for Fc receptors but also for immunologically important receptors generally. There have been several major milestones in the application of new technologies to the characterization of Fc receptors – Jay Unkeless produced the first monoclonal antibody defining an Fc receptor and Hibbs and colleagues defined first function associated genetic polymorphism using monoclonal antibodies. The genetics revolution led to the first cloning in the mid-1980s of the FcR gene simultaneously and independently by Hibbs, Ravetch, Mellman, and Kinet. By the early 1990s, Ierino and coworkers had established that blockade of FcR may provide useful therapeutic approaches for the treatment of disease. Finally, in more recent times, the discovery of the elusive IgM receptor by Kubagawa and co-workers as well as the three-dimensional structures of FcR have become available for the first time through the work of Maxwell and Powell, Jardetzky, Sun, Sonderrmann, and others.

Conclusion

The FcRs are a large family of immunoregulatory molecules that play crucial roles in antibody effector systems, leading in normal immune responses to the activation or regulation of leukocytes.

Indicators of Intracellular Calcium

M Giacomello and M Campeol, University of Padua and Venetian Institute of Molecular Medicine, Padua, Italy

© 2013 Elsevier Inc. All rights reserved.

Glossary

BAPTA 1,2-bis(*o*-aminophenoxy)ethane-*N,N,N',N'*-tetraacetate is a calcium and magnesium chelator.

EF hand An helix–loop–helix motif present in many Ca^{2+} -binding proteins. As a rule, this domain consists of two alpha helices orthogonal to one another and linked by a stretch of about 12 amino acids that bind Ca^{2+} ions.

EGTA The Ca^{2+} chelator ethylene glycol-*O,O'*-bis (2-amino-ethyl)-*N,N,N',N'*-tetraacetic acid.

Fluorescence resonance energy transfer (FRET) Known also as Förster resonance energy transfer. It is the nonradiative energy transfer between a donor and an acceptor chromophore. This process requires a partial overlap in the emission spectrum of the donor and the excitation spectrum of the acceptor. In addition, the two chromophores should be positioned close enough (usually less than 10 nm) and have the appropriate relative orientation.

Introduction

Many physiological and pathological processes are linked to variations of the intracellular Ca^{2+} homeostasis. In addition to its structural role (e.g., in bones and teeth), the Ca^{2+} ion has a crucial role as a cell messenger. Its signaling ability relies on the possibility to shape the changes of its concentration in terms of amplitude, kinetics, and spatial pattern. This is accomplished by a wide number of proteins located in the cell membranes, in the cytosol, and in the subcellular compartments, such as the mitochondria and the endoplasmic reticulum (ER). The need to monitor the variations of this highly dynamic system has led to the development of specific indicators with different affinities for Ca^{2+} , adequate to analyze a wide range of its intracellular free concentration ($[\text{Ca}^{2+}]$). The possibility to choose molecules with various affinities (K_d) is particularly important, as $[\text{Ca}^{2+}]$ levels are highly heterogeneous not only inside the cytoplasm, where the presence of micropools with high $[\text{Ca}^{2+}]$ has been demonstrated, but also within organelles as the ER and Golgi, that are considered the major intracellular Ca^{2+} stores.

Ca^{2+} probes bind the ion reversibly and, as a consequence, vary their physicochemical characteristics. Among the physicochemical properties that characterize Ca^{2+} sensors, the most common is the difference in the emission and/or absorbance of light induced by the binding of Ca^{2+} . Thus, the changes in the intracellular $[\text{Ca}^{2+}]$ are defined by the respective amount of the two forms of the sensor, that is, the Ca^{2+} -bound and the Ca^{2+} -free form.

Ca^{2+} indicators can be classified according to different criteria: they could be nonratiometric and ratiometric, chemical (synthetic; Table 1) and genetically encoded (Table 2).

In nonratiometric molecules only one of their properties, for example, their fluorescence intensity, varies as a consequence of Ca^{2+} binding. Experiments with them are simple: the acquisition system needed to collect data involves a single excitation/emission setting. However, nonratiometric molecules fail to correct for the different absolute amount of dye loading that can vary from cell to cell or for focal plane shifts that could be present. On the contrary, ratiometric probes correct for these drawbacks: upon interaction with Ca^{2+} two

parameters, most commonly the excitation and emission spectra, vary simultaneously. In ratiometric measurements, the variations of $[\text{Ca}^{2+}]$ are proportional to the changes of the ratio between the two fluorescence intensity values.

The analysis of the synthetic and the genetically encoded Ca^{2+} indicators demands a more extensive discussion.

Chemical Indicators

The first sensors used to monitor cellular $[\text{Ca}^{2+}]$ variations have been organic compounds like murexide and azo dyes. Murexide, also known as ammonium purpurate or MX, is the ammonium salt of purpuric acid. This metallochromic indicator undergoes a color change in the presence of calcium. A similar behavior characterizes the azo dyes, that contain nitrogen in the form of an azo group ($-\text{N}=\text{N}-$) as part of their molecular structure. These two classes of molecules have been used for some years for the titration of Ca^{2+} , but have poor emission intensity and signal-to-noise ratio. Chlortetracycline, an antibiotic also used as a Ca^{2+} sensor, had higher changes in fluorescence intensity but its poor selectivity (it also interacts with Mg^{2+}) and its sensitivity to alterations of the membrane potential and pH limited its use.

In the 1980s, Roger Y Tsien synthesized the first fluorescent polycarboxylate Ca^{2+} indicators. These probes were designed starting from the structure of the selective Ca^{2+} chelator EGTA. The replacement of two methylene groups with two benzene rings leads to the building of a chromophore moiety. In these indicators, Ca^{2+} binding to the carboxyl groups changes the optical properties of the molecule. The parent compound of these polycarboxylate probes, BAPTA, displays large spectral shifts on Ca^{2+} binding and requires ultraviolet excitation, which is more cytotoxic than longer wavelengths. In addition, ultraviolet irradiation causes emission of intrinsic fluorescence by endogenous cell molecules, such as NADH (reduced nicotinic adenine dinucleotide; excitation at 340 nm and emission peaks at 440–470 nm). The presence of autofluorescence leads to inaccuracy in the fine estimation of the variations of free $[\text{Ca}^{2+}]$.

Quin 2, a tetracarboxylic acid derivative of quinoline, is one of these first-generation Ca^{2+} probes. As is the case for the

other sensors, binding of Ca^{2+} leads to changes of some of the spectral properties of the compound, that is, to an emission maximum at 492 nm and to a considerable enhancement of the fluorescence emission intensity. Quin 2 has a very high affinity for Ca^{2+} (K_d 115 nM) making it ideal for studying $[\text{Ca}^{2+}]$ variations in intracellular resting concentration (100–200 nM). However, the low K_d affects the reliability of $[\text{Ca}^{2+}]$ measurements at μM levels as they may cause saturation of the sensor. In addition, the excitation wavelength of Quin 2 peaks at 339 nm and causes the appearance of significant autofluorescence. In conjunction with its low absorption coefficient, this leads to a poor signal-to-noise ratio, unless the cells are loaded with high amounts of the probe. For these reasons, Quin 2 started to be used more as an intracellular Ca^{2+} buffer rather than a real Ca^{2+} indicator. To overcome the problems of Quin 2, Tsien and coworkers synthesized new Ca^{2+} probes that combined a stilbene fluorophore with the structure of

the Ca^{2+} chelators EGTA and BAPTA. A new family of Ca^{2+} -binding molecules were thus obtained, among them Indo 1 and Fura, that had much higher brightness of fluorescence (about 30 times higher than Quin 2), with wavelength shifts upon Ca^{2+} binding and/or weaker affinity for Ca^{2+} .

Indo 1 is a BAPTA derivative with an increased fluorescence quantum yield with respect to Quin 2. $[\text{Ca}^{2+}]$ measurements with Indo 1 exploit the shift of emission wavelength from 475 to 401 nm upon Ca^{2+} binding. The fluorescence intensity ratio at the two wavelengths is proportional to the intracellular $[\text{Ca}^{2+}]$ changes and corrects for unequal dye loading or changes in the volume and shape of the cells. Three major problems unfortunately complicate the use of Indo 1: its rapid photobleaching, its photodegradation, and significant autofluorescence of cell components due to the excitation wavelengths used. While photobleaching of the indicator causes a decrease in the signal-to-noise ratio, the degradation

Figure 1 (a) Ratiometric image of HeLa cells loaded with 3 μM FURA2-AM under resting conditions. (b, c) In cells challenged with an agonist coupled to InsP3 production (as the purinergic agonist adenosine triphosphate (ATP)), Ca^{2+} is released from the endoplasmic reticulum (ER), leading to an increase of the cytosolic $[\text{Ca}^{2+}]$, which is reflected by the increased ratio. The trace in panel c represents the typical response of a cell loaded with FURA2-AM and challenged with 100 μM ATP, in a standard medium containing 1 mM Ca^{2+} .

by ultraviolet illumination renders the fluorescence of Indo 1 Ca^{2+} insensitive. This results in an underestimation of the true intracellular $[\text{Ca}^{2+}]$. The autofluorescence issue is also important, as both the excitation and the emission spectra of NADH overlap with those of Ca^{2+} -free Indo 1, leading to the increase of autofluorescence background.

Fura is also excited by ultraviolet illumination. Three different Fura molecules were generated: Fura 1, Fura 2, and Fura 3: the most commonly used is Fura 2 (Figure 1). This ratiometric probe has a K_d for Ca^{2+} of 224 nM and shifts absorption peak upon Ca^{2+} binding from 363 to 335 nm, the emission peak remaining unvaried. Dual excitation of Fura 2 is achieved at 340 and 380 nm since the absorption peaks at these wavelengths are closer to its isosbestic point. Other Fura 2 variants have been created in order to study signal transduction processes that involve Ca^{2+} spikes exceeding 1 μM values. One of these compounds, bis-Fura, was obtained by joining together one Ca^{2+} -binding site and two Fura 2 fluorophores. The lower K_d for Ca^{2+} of this probe decreases its Ca^{2+} -buffering activity. In addition, the higher changes in the ratio of bis-Fura 2, with respect to Fura 2, allows to lower the amount of dye to be loaded into the cells.

Furaptra, also called Mag Fura 2, had been originally designed to report changes in intracellular Mg^{2+} concentration (it binds it with a K_d of 1.9 mM). However, Mag Fura 2 also binds Ca^{2+} with a K_d of 25 μM . Since its K_d is well above the

physiological basal Ca^{2+} levels of most cells, Furaptra has been widely used to monitor intracellular Ca^{2+} variations in the range between 1 and 100 μM or to evaluate fast changes in the free $[\text{Ca}^{2+}]$, for instance in skeletal muscle during electrical stimulation.

In addition to ultraviolet light excited indicators, some compounds excited by visible wavelength have also been generated. Visible light causes lower cytotoxicity and lower background scattering than ultraviolet light. Among the visible light excited Ca^{2+} probes, Fluo3 and Fluo4, Calcium green and Oregon green BAPTA are the most commonly used. Fluo3 and Fluo4 share a similar structure. They are nonratiometric Ca^{2+} sensors that increase fluorescent emission intensity on Ca^{2+} binding. They have a relatively high K_d (400 and 345 nM, respectively) that accounts for the absence of Ca^{2+} -buffering activity under resting conditions. They differ in pH sensitivity and fluorescence, Fluo4 being more photostable and brighter than Fluo3. The Calcium green family of Ca^{2+} probes (that comprises Calcium green 1, 2, and 5 N, having different Ca^{2+} affinities) has higher quantum yield and brighter fluorescence at saturating amounts of Ca^{2+} than Fluo3 and Fluo4. Oregon green BAPTA is another family of indicators based on BAPTA (including Oregon green BAPTA-1 and -2) excited by a visible-wavelength Ca^{2+} indicator. These molecules have considerable photostability and low pH sensitivity, which affect other indicators like Fluo3. In addition to the problems of cytotoxicity,

pH sensitivity, and photodegradation, the main drawback in the use of chemical Ca^{2+} indicators is the method to introduce them inside living cells and the inability to target them to particular subcellular compartments. Synthetic Ca^{2+} probes have been introduced into the cytoplasm by techniques such as microinjection, transfer through liposomes, and electroporation. However, the transformation of virtually all the Ca^{2+} probes cited above into the acetoxymethyl (AM) ester form has greatly increased their popularity. Once in the cytoplasm, the AM forms of the probes undergo cleavage by intracellular esterases, leading to the release of the original form of the indicator in the cytoplasm, where it remains trapped since it is membrane impermeable. It is widely assumed that the AM forms of the dyes are completely cleaved but incomplete de-esterification cases have been reported, causing the permanence of Ca^{2+} -insensitive fluorescent molecules as well as the accumulation of the probe inside cell compartments as the mitochondria or the ER. The finding that AM dyes could be in part trapped into organelles has been actually exploited to address them to specific subcellular localizations. Blum and coworkers have, for instance, targeted AM-linked Ca^{2+} indicators to the ER using the targeted-esterase induced dye loading (TED) technique. The technique requires the expression of recombinant esterases into the ER and the loading of the cells with a Ca^{2+} indicator in the AM form: upon cleavage, the probe remains in the lumen of the organelle. In some cases, the chemical properties of the Ca^{2+} -binding molecule allow for its accumulation into specific cellular compartments. For example, the AM forms of X-Rhod 1 and Rhod 2, two members of the Rhod family of Ca^{2+} indicators, are positively charged and thus tend to be sequestered inside mitochondria. Furthermore, their low affinity (K_d of about 700 and 570 nM, respectively) makes them ideal for the measurement of $[\text{Ca}^{2+}]$ changes inside the mitochondrial matrix.

Genetically Encoded Ca^{2+} Indicators

Genetically encoded Ca^{2+} indicators (Table 2) can be easily introduced into cells and can be selectively targeted to specific subcellular compartments. They can be divided into two main families: bioluminescent and green fluorescent protein (GFP)-based probes. Both groups are based on proteins derived from biological organisms: for example, Obelin was found in the hydrozoa *Obelia geniculata*, while aequorin and the GFP have been extracted from the jellyfish *Aequorea victoria*. Molecular biology techniques have made possible to clone the coding sequence of these proteins, to modify their properties by introducing point mutations, and to overexpress them in model cells. They have also made it possible to modulate the pattern and the timing of their expression by tissue-specific or inducible promoters and to target them to specific organelles by coupling them to appropriate lead sequences.

Bioluminescent Probes

Bioluminescent probes are based on the production of light by an intramolecular reaction. They do not suffer the photobleaching problems that affect chemical probes (and also the

Figure 2 Schematic representation of photon emission from aequorin upon Ca^{2+} binding. The chemical structure depicted within the Aequorin molecule is the prosthetic group coelenterazine. The receptor-like structures on the surface of Aequorin represent the EF hand motifs that bind calcium.

GFP-based Ca^{2+} probes, see below). Obelin and aequorin, the most commonly used bioluminescent proteins, consist of a single polypeptide chain that hosts three EF hands Ca^{2+} -binding domains. They are apoproteins that need binding of a cofactor, coelenterazine, to become active. Following interaction with Ca^{2+} , conformational changes in the protein trigger the peroxidation of coelenterazine, which is oxidized to coelenteramide and is released with the concomitant emission of a photon (Figure 2). This reaction inactivates the photoprotein irreversibly. The luminescent signal supplies the raw data from which the $[\text{Ca}^{2+}]$ levels are then estimated with an algorithm that considers the exponential correlation between $[\text{Ca}^{2+}]$ and the amount of emitted light. Obelin and aequorin differ in their emission wavelength (466 nm for aequorin; 495 for obelin), in their sensitivity for Ca^{2+} , which is lower in the former, and in the speed in the emission of light, which is faster in obelin (3 ms vs. 10 ms). These properties make obelin more suitable for studies that require high temporal resolution, while aequorin is more adequate for $[\text{Ca}^{2+}]$ measurements in 0.5–10 μM Ca^{2+} concentration range. Mutated forms of aequorin have been created to study Ca^{2+} variations in the 10–100 μM range. Furthermore, the use of a coelenterazine analog (coelenterazine n) makes it possible to monitor Ca^{2+} concentrations up to a millimolar. By fusing its complementary DNA (cDNA) with specific intracellular targeting signals, it has been targeted to the nucleus, the ER, the Golgi apparatus, the plasma membrane, the peroxisomes, and even to different positions inside mitochondria, for example, the matrix and the intermembrane space.

In general, since each bioluminescent Ca^{2+} -binding protein only emits one photon when it binds Ca^{2+} , the emission intensity is quite low, ruling out single-cell measurements and only allowing cell-population studies.

GFP-Based Ca^{2+} Probes

Soon after the discovery of the GFP, its potential to detect intracellular events became obvious. GFP is composed of 238 amino acids organized in an 11-stranded beta barrel structure. The chromophore of the protein is not an independent prosthetic group, but it is formed by amino acids of the polypeptide chain itself. These residues were identified as Serine 65,

Tyrosine 66, and Glycine 67, arranged in the center of the beta barrel structure. The fluorophore emits green fluorescence when challenged with blue light. The introduction of point mutations in the fluorophore moiety of GFP produces changes in the spectral properties of the fluorophore and has led to the production of numerous variants of the fluorescent protein. For example, the Y66H and Y66W replacement lead to the generation of a blue fluorescent protein (BFP) and ciano fluorescent protein (CFP), respectively. The T203Y replacement caused a shift of the excitation and emission spectra to higher wavelengths: the protein carrying this mutation is the yellow fluorescent protein (YFP). YFP is peculiar since it is more sensitive to photobleaching, pH, and chloride ions than GFP. Some commonly used analogs of YFP are Citrine and Venus. These variants have a lower pH and chloride sensitivity and faster maturation rates.

The fluorescent variants of GFP have set the basis for the development of other Ca^{2+} indicators, among which the most commonly used are the Camgaroos, the Pericams, and the Cameleons.

The Ca^{2+} indicators known as 'Camgaroos' comprise Camgaroo-1 and -2. They are based on a single fluorescent protein: YFP. Camgaroos were generated by exploiting the finding that the introduction of peptides at the level of amino acid 145 of GFP does not interfere with its ability to fluoresce. Thus, YFP was split into an N-terminal moiety, comprising amino acids 1–144, and a C-terminal domain, from amino acid 145 to the end of the polypeptide chain. These two portions of the YFP molecule were then fused to the N and C terminus of the Ca^{2+} -binding protein Calmodulin, respectively. Ca^{2+} binding to the grafted Calmodulin induces the deprotonation of the chromophore, leading to the increase in the amplitude of both excitation and emission spectra but without shifts in peak wavelength.

Another group of Ca^{2+} sensors, ratiometric Pericams, instead take advantage of another type of modification in the YFP structure, that is, circular permutation. The latter involves the interchange of the N and C terminus of the protein: in the case of YFP, the circularly permuted fluorophore is not only able to fluoresce as in the original protein, but it also shows efficient maturation and higher stability in acidic pH. In Pericams, Calmodulin is fused in tandem to the C terminus of the circularly permuted YFP (cpYFP), while a peptide derived from the Calmodulin-binding domain of the skeletal muscle myosin light chain kinase (known as M13) is present ahead of the N terminus of the cpYFP. When $[\text{Ca}^{2+}]$ levels rise, the M13 peptide interacts with Calmodulin, causing a conformational change of the whole fusion protein that induces variations in the fluorescence of cpYFP.

The most popular members of the Pericam family are ratiometric Pericams and inverse Pericam. Ratiometric Pericam has a bimodal excitation spectrum (415 and 494 nm), and the relative intensities of the emission light change in the transition from the Ca^{2+} -bound to the Ca^{2+} -free forms, allowing for ratiometric measurement. Inverse Pericam instead is a nonratiometric Ca^{2+} probe that decreases the fluorescence intensity on Ca^{2+} binding. One important problem linked to the use of Pericams in living cells is their pH sensitivity. Another is the possibility that endogenous Calmodulin partners could recognize the exogenous Calmodulin moiety of the Ca^{2+} probe and interact with it.

The third class of GFP-based Ca^{2+} indicators, yellow Cameleons (YC), includes two different GFP variants (typically CFP and YFP) linked by Calmodulin and M13. The ability of these ratiometric probes to measure Ca^{2+} levels relies on a fluorescence resonance energy transfer (FRET), which defines the mechanism of nonradiative energy transfer between two fluorophores. In particular, the excited donor chromophore (which is CFP in the Cameleon probe) transfers energy to the acceptor chromophore (YFP). In the case of Cameleons, Ca^{2+} -binding causes Calmodulin and M13 to wrap around each other, bringing CFP and YFP closer and allowing FRET to occur. In these conditions, the fluorescence intensity emission of CFP decreases and the emission of YFP increases: the ratio between the two is proportional to $[\text{Ca}^{2+}]$ levels. Also with Cameleons, the main problem is their interaction with endogenous Calmodulin/M13 partners, that could cause artifacts in the evaluation of intracellular Ca^{2+} changes.

Heim and coworkers have developed a particular class of FRET-based Ca^{2+} probes, in which the molecular switch, instead of Calmodulin and M13, is Troponin c. This muscle protein is predicted to have no interacting partners in other cell types. Among the Troponin c-based Ca^{2+} indicators, Tn-XXL seems particularly promising since it has been successfully expressed both *in vivo* and *in vitro*.

To solve the problem of interactions between endogenous proteins and Ca^{2+} probes, a new generation of Cameleons has been created, in which the interaction domains of M13 and calmodulin have been point mutated. The amino acid substitutions have led to the development of novel variants of the probes with different Ca^{2+} affinities. To increase the brightness of these new Ca^{2+} probes, YFP has been replaced by its circularly permuted analog, Venus, providing an increased dynamic range. By means of targeting sequences, Cameleons have been addressed to various organelles, such as the ER, mitochondria, peroxisomes, nucleus, as well as to the space beneath the plasma membrane.

One last advance in the development of GFP-based Ca^{2+} probes has been recently reported by J J Yang. The addition of negatively charged residues, such as those that typically compose Ca^{2+} -binding sites, to the GFP chromophore affects both its maturation and fluorescence properties. J J Yang and coworkers have introduced Ca^{2+} -binding motifs into the structure of GFP, laying the foundations for the development of a novel class of GFP-based Ca^{2+} indicators.

Conclusions

Ca^{2+} indicators have come a long way from the development of the first Ca^{2+} probes. The availability of genetic and molecular biology techniques coupled to cell biology strategies to deliver recombinant probes inside cell compartments have greatly advanced the study of Ca^{2+} signaling. While the first compounds had to be microinjected into cells, loading of the cells can now be easily obtained by transfection or viral infection. The GFP-based probes have allowed the analysis of the contribution of single intracellular compartments to the overall cellular Ca^{2+} homeostasis process. A caveat is, however, necessary: Ca^{2+} measurement experiments must be carefully

designed in order to choose the more appropriate indicator. Each Ca^{2+} probe has both advantages and disadvantages and the ideal Ca^{2+} indicator for living cells or tissue slices has not been developed yet. The necessity to monitor $[\text{Ca}^{2+}]$ variations in whole organs or tissue will require the development of novel sensors, suitable for the measurements of $[\text{Ca}^{2+}]$ in living organisms.

Inositol Phosphate Kinases and Phosphatases

S B Shears, NIEHS, Research Triangle Park, NC, USA

Published by Elsevier Inc.

Glossary

Diphosphoinositol polyphosphate A type of inositol phosphate that has either one or two diphosphate (pyrophosphate) groups.

Inositol phosphate A compound with a six-member carbon ring structure to which single phosphates (and sometimes diphosphates) are attached at various positions.

Inositol phosphate kinase An enzyme that transfers a phosphate group from adenosine triphosphate to the inositol ring.

Inositol phosphate phosphatase An enzyme that removes a phosphate group from the inositol ring.

Inositol phosphate phosphotransferase An enzyme that transfers a phosphate from one inositol phosphate to another – a specific property of ITPK1.

Intracellular signal/messenger One member of what is usually a functionally coupled series of molecules or ions that together comprise a chemical pathway which conveys and amplifies a cell's biological response to a specific extracellular stimulus, such as a hormone or neurotransmitter.

Phospholipase C A specialized enzyme that releases Ins(1,4,5)P₃ from its membrane tether.

Phytic acid The nonsystematic but widely used alternate name for InsP₆; the molecule formed by filling all six carbons of the inositol ring with single phosphate groups.

Turtle A marine reptile that provides a visual mnemonic for easy recall of the nomenclature for numbering the carbon atoms that comprise the inositol ring.

Introduction

Information transfer in biological systems – a process frequently termed signal transduction – requires sensor proteins to detect and respond to regulatory input from an effector, which can be either another protein or a small molecule. The ability of a sensor to perceive an effector is frequently dependent upon a recognition pattern generated by the presence or absence of phosphate groups. When one or more of these phosphate groups are added (phosphorylation) or removed (dephosphorylation) from the effector, such a process acts as a molecular switch that determines whether the regulator is 'on' or 'off'. Inositol (Figure 1) is an example of a small molecule that is functionally modified in this manner. Each of the six hydroxyl groups that are attached to the carbons of the *myo*-inositol ring (Figure 1(a)) are sites for phosphorylation. Enzymes that add phosphate groups to the inositol moiety are known as inositol phosphate kinases. A separate family of enzymes, the inositol phosphate phosphatases, removes phosphate groups from the inositol ring. Phosphate-transfer reactions catalyzed by these phosphatases and kinases are networked in serial and parallel configurations, permitting the cell to add and subtract phosphate groups in a combinatorial manner, thus generating an array of inositol phosphate molecules. Recognition patterns, which arise from specific topographical arrangements of phosphate groups around the inositol ring, endow certain inositol phosphates with specific, biologically important functions, often in the context of signal transduction. Thus, inositol phosphate kinases and phosphatases control the synthesis and metabolism of important effector molecules.

Inositol Phosphate Nomenclature

To appreciate the nature of phosphate recognition patterns around the inositol ring, it is necessary to understand the nomenclature that distinguishes the different carbons that comprise the inositol moiety. Fortunately, Agranoff's turtle (Figure 1) provides us with a timeless, visual mnemonic. In this *aide mémoire*, the hydrogens are conveniently ignored and the inositol ring is depicted in its thermodynamically stable so-called chair conformation (Figure 1(b)). The structure's resemblance to a turtle is then apparent (Figure 1(c)). As a consequence of deliberations by international nomenclature committees, the turtle's appendages are numbered in an anti-clockwise direction (when viewed from above), commencing with the front right flipper. The 2-hydroxyl (the turtle's head) is axial to the plane of the ring, whereas the other five hydroxyls (the four flippers and the tail) are equatorial (i.e., approximately in the same plane as the ring). This numbering system allows us to readily and unambiguously specify the location of phosphate groups that are added to the inositol ring. Ins(1,4,5)P₃, for example (see Figure 2), is an abbreviation that describes the addition of three single phosphate groups (P₃) to the inositol (Ins) ring, at positions 1, 4, and 5. Ins(1,2,3,4,5,6)P₆ describes the molecule in which all six of the carbons are attached to single phosphate groups, but since this feature makes the numbering superfluous, InsP₆ is the acceptable definition (Figure 2). This particular inositol phosphate is also widely known as phytic acid. Some inositol phosphates even contain diphosphate (i.e., PP) groups (Figure 2), the so-called 'inositol pyrophosphates' or, more correctly, diphosphoinositol polyphosphates.

Figure 1 Inositol ring nomenclature. (a) Complete chemical structure of inositol; (b) naturally occurring conformation of inositol, *sans* hydrogens; (c) the numbering of the turtle's appendages in an anti-clockwise direction (beginning with its right flipper) provides an *aide m  moire* for inositol phosphate nomenclature.

Enzyme Nomenclature and Metabolic Interrelationships

Figure 2 provides a metabolic map showing the participation of those inositol phosphate kinases and phosphatases that are most commonly found across the phylogenetic spectrum. Unfortunately, these enzymes are not always named either in a manner that is both universally accepted or by a system that unambiguously describes their function(s). For example, the names IPK1 and IPK2 do not designate the positional specificities of these kinases, but instead merely reflect the chronological order in which a particular team of researchers identified these kinases. There is another enzyme that removes the 5-phosphate from both $\text{Ins}(1,4,5)\text{P}_3$ and $\text{Ins}(1,3,4,5)\text{P}_4$. However, inositol polyphosphate 5-phosphatase is a popular terminology for this enzyme, despite the fact that this exaggerates its promiscuity, by erroneously implying that the enzyme removes the 5-phosphate from other inositol phosphates. The preferred, unambiguous nomenclature for this enzyme is $\text{Ins}(1,4,5)\text{P}_3/\text{Ins}(1,3,4,5)\text{P}_4$ 5-phosphatase (**Figure 2**). Nevertheless, such a systematic approach does become unwieldy when a single enzyme metabolizes three or more substrates, especially when the positional specificity of the enzyme varies with the nature of the substrate. For example, there is a single kinase that adds a 3-phosphate to $\text{Ins}(1,4,5)\text{P}_3$, a 6-phosphate to $\text{Ins}(1,3,4,5)\text{P}_4$, a 5-phosphate to $\text{Ins}(1,3,4,6)\text{P}_4$, and a

Figure 2 Metabolic interrelationships of inositol phosphate kinases and phosphatases. The figure provides a metabolic map showing the participation of some important inositol phosphate kinases and phosphatases that are widely distributed across the phylogenetic spectrum. The numbers associated with each arrow represent the following enzymes: 1, inositol monophosphatase; 2, $\text{Ins}(1,4)\text{P}_2/\text{Ins}(1,3,4)\text{P}_3$ 1-phosphatase; 3, $\text{Ins}(1,3)\text{P}_2$ 3-phosphatase; 4, $\text{Ins}(3,4)\text{P}_2/\text{Ins}(1,3,4)\text{P}_3$ 4-phosphatase; 5, $\text{Ins}(1,4,5)\text{P}_3/\text{Ins}(1,3,4,5)\text{P}_4$ 5-phosphatase; and 6, IPMK, for inositol polyphosphate multikinase. Also known as IPK2; 7, $\text{Ins}(1,4,5)\text{P}_3$ 3-kinase; 8, ITPK1; 9, MIPP, for multiple inositol polyphosphate phosphatase; 10, PTEN (for phosphatase and tensin homolog, deleted on chromosome ten); 11, IP6K, for inositol hexakisphosphate kinase; 12, DIPP, for diphosphoinositol polyphosphate phosphohydrolase; and 13, IP5K, for $\text{Ins}(1,3,4,5,6)\text{P}_5$ 2-kinase. Also known as IPK1; 14, PPIP5K (for diphosphoinositol pentakisphosphate kinase), and sometimes described as VIP.

3-phosphate to $\text{Ins}(1,4,5,6)\text{P}_4$. For brevity, this protein is often known as the 'inositol polyphosphate multikinase' (**Figure 2**). Equally, the phosphatase that specifically removes the 3-phosphate from $\text{Ins}(1,3,4,5,6)\text{P}_5$ and the 6-phosphate from $\text{Ins}(1,4,5,6)\text{P}_4$ is also capable of removing any of the phosphate groups from InsP_6 ; this enzyme is known as the 'multiple inositol polyphosphate phosphatase'. ITPK1 is another enzyme that deserves special mention. It was originally named from its ability to phosphorylate $\text{Ins}(1,3,4)\text{P}_3$. The name has remained unaltered even as our insight into the enzyme's full catalytic repertoire has considerably expanded.

Now we know it also phosphorylates $\text{Ins}(3,4,5,6)\text{P}_4$ and, perhaps most remarkably of all, ITPK1 also acts as a phosphotransferase, exchanging phosphate groups between $\text{Ins}(1,3,4,5,6)\text{P}_5$ and $\text{Ins}(1,3,4,6)\text{P}_4$. Finally, the name of one of this family of enzymes – PTEN (phosphatase and tensin homolog deleted on chromosome 10) – does not specifically address its ability to metabolize an inositol phosphate. That nomenclature reflects some other characteristics of this enzyme which were established before its $\text{Ins}(1,3,4,5,6)\text{P}_5$ 3-phosphatase activity was clarified (see [Figure 2](#)).

Although the inositol phosphates are generally considered to be freely diffusible molecules, some of the enzymes that metabolize them can often be found to be concentrated in specific regions of the cell. This creates a cell-signaling paradox. Why segregate one component of a cell-signaling apparatus, in order to generate a second messenger that then freely diffuses throughout the entire cell? Providing an answer to this question is one of the challenges for future work in this field. In part, enzyme compartmentalization may reflect some additional, noncatalytic role, for example, as a molecular scaffold around which higher-order multimeric complexes can be constructed.

Regulatory Input into the Inositol Phosphate Pathway

There are two separate metabolic routes that feed into the pathway shown in [Figure 2](#): the first is by enzymatic conversion of glucose-6-phosphate into $\text{Ins}3\text{P}$ and the second is synthesis of $\text{Ins}(1,4,5)\text{P}_3$. The latter is initially attached through its 1-phosphate (i.e., its front right flipper, [Figure 1\(c\)](#)) to the lipid material that represents the bulk phase of cellular membranes. This attachment is severed by a specialized enzyme – a phospholipase C – that is stimulated when a hormone or neurotransmitter binds to appropriate receptors on the cell surface. The $\text{Ins}(1,4,5)\text{P}_3$ released by phospholipase C has

the role of liberating cellular stores of calcium, which, in turn, regulates many calcium-dependent cellular processes. The efficacy of $\text{Ins}(1,4,5)\text{P}_3$ depends upon its intracellular concentration, which, in turn, is dictated by a dynamic balance between competing rates of $\text{Ins}(1,4,5)\text{P}_3$ synthesis (by phospholipase C) and metabolism (by inositol phosphate kinases and phosphatases; [Figure 2](#)). Hormones and neurotransmitters also use cell-surface receptors to activate the synthesis of many other intracellular chemical messengers, and these can lead to changes in the activities of several inositol phosphate kinases and phosphatases. The activities of some of these enzymes can also respond to stimuli that are generated from within cells, such as those that arise following a decline in bioenergetic health. Through these various regulatory processes, the cell can carefully regulate metabolic flux through specific areas of the inositol phosphate pathway, thereby manipulating levels of inositol phosphates which are themselves intracellular signals (see section [Further Reading](#)).

Glossary

2-Aminoethoxydiphenyl borate (APB) A pharmacological agent used to inhibit the release of Ca^{2+} by the InsP_3 receptors.

Ca^{2+} -induced Ca^{2+} release (CICR) A regenerative mechanism whereby Ca^{2+} triggers release of further Ca^{2+} .

Endoplasmic reticulum (ER) Internal membrane sacs that store Ca^{2+} .

G-protein-coupled receptors (GPCRs) Cell-surface receptors that responds to external stimuli such as hormones and neurotransmitters.

Inositol 1,4,5-trisphosphate (InsP_3) A Ca^{2+} -mobilizing second messenger.

Phospholipase C (PLC) An enzyme that hydrolyzes a membrane phospholipid to release the Ca^{2+} -mobilizing second-messenger inositol 1,4,5-trisphosphate (InsP_3).

Ryanodine receptor (RyR) Calcium release channels locate in the ER.

Cellular Ca^{2+} signaling systems are characterized by their variety and specificity. Each cell type has a unique system specifically designed to control its particular function. All of these Ca^{2+} control systems are variations on a basic theme where the level of Ca^{2+} is low in resting cells and is rapidly elevated in response to external stimuli. Much of the specificity of Ca^{2+} signaling depends on how this surge in Ca^{2+} is organized in both time and space. For example, a brief microsecond pulse of Ca^{2+} restricted to the synaptic endings of neurons triggers the release of neurotransmitters. Ca^{2+} sparks, located specifically at the junctional zones in cardiac cells, are fired synchronously in less than a second to produce the localized pulses of Ca^{2+} to drive cardiac contraction. At the other end of the temporal scale, much slower global Ca^{2+} signals, often spreading as regenerative Ca^{2+} waves, function over many seconds to minutes to control the cell cycle as occurs during mammalian fertilization. This great variety and versatility of the Ca^{2+} signaling systems depends on an extensive Ca^{2+} signaling toolkit. During cell differentiation, different components of this toolkit are selected to create specific signaling systems. One of the basic modules found in many different cell types is the inositol 1,4,5-trisphosphate (InsP_3)/ Ca^{2+} signaling system.

InsP_3 Formation

The main mechanisms responsible for forming the Ca^{2+} -mobilizing second messenger InsP_3 are shown in **Figure 1**. External stimuli (e.g., hormones, neurotransmitters, and growth factors) gain access to this signaling pathway by activating cell-surface receptors. The latter fall into two main classes: the G-protein-coupled receptors (GPCRs) and the protein-tyrosine kinase-linked receptors (PTKRs). During the transduction process, these receptors activate phospholipase C (PLC) that hydrolyses the precursor lipid phosphatidylinositol 4,5-diphosphate ($\text{PtdIns}4,5\text{P}_2$) to generate InsP_3 , which then diffuses into the cytosol to activate the InsP_3 receptors to release Ca^{2+} stored in the endoplasmic reticulum (ER).

There is a family of PLCs that can be distinguished by the way they are coupled to cell-surface receptors. In general, the

GPCRs use the PLC β isoforms, whereas the PTKRs are coupled to the PLC γ isoforms. Various other input signals are responsible for activating some of the other PLC isoforms. For example, PLC δ 1 appears to be activated by an elevation in cytosolic Ca^{2+} , and PLC ϵ is activated by GTP-binding proteins such as Ras and Rap1A. The second messenger cyclic adenosine monophosphate (cAMP) acts through the exchange protein activated by cAMP (EPAC) protein to stimulate Rap1 to activate PLC ϵ . The PLC ζ isoform, which is expressed in mammalian sperm, is injected into eggs following sperm-egg fusion to generate the InsP_3 that activates oocytes during fertilization.

InsP_3 Metabolism

The InsP_3 that is formed during signaling is removed by various inositol phosphate metabolic pathways from which it emerges either as free inositol or as various inositol polyphosphates, such as InsP_4 , InsP_6 , InsP_7 , and InsP_8 (**Figure 2**). The InsP_3 that enters these various pathways is metabolized initially by two different enzymes. It is dephosphorylated by type I inositol polyphosphate 5-phosphatase to form $\text{Ins}1,4\text{P}_2$. This InsP_3 phosphatase is directed to the membrane by isoprenylation of the C-terminal region. If these membrane-attachment sites are removed, allowing the enzyme to disperse into the cytosol, InsP_3 metabolism appears to be severely curtailed. It seems that much of the InsP_3 is metabolized close to its site of action at the plasma membrane. The $\text{Ins}1,4\text{P}_2$ is then dephosphorylated further to produce free inositol that is used to resynthesize PtdIns , which is the lipid precursor used to generate the $\text{PtdIns}4,5\text{P}_2$ – the substrate for PLC to generate InsP_3 . Cells have access to three separate sources of inositol: recycling the second messenger InsP_3 (as just described), *de novo* synthesis from glucose 6-phosphate, or uptake of dietary inositol circulating in the plasma. Drugs, such as lithium and valproate, may control manic-depressive illness by reducing the supply of inositol by inhibiting inositol monophosphatase and inositol synthase, respectively. The supply of free inositol is one of the essential precursors for the synthesis of PtdIns , which is transferred from its site of synthesis on the ER to

Figure 1 Inositol 1,4,5-trisphosphate (InsP₃) and Ca²⁺ signaling. G-protein-coupled receptors (GPCRs) and the protein tyrosine kinase-linked receptors (PTKRs) activate different phospholipase C (PLC) isoforms. InsP₃ activates the InsP₃ receptor (InsP₃R) to release Ca²⁺ from the endoplasmic reticulum (ER). During the recovery phase, Ca²⁺ is pumped out of the cell or is returned to the ER.

the plasma membrane by PtdIns transfer protein (PITP) (Figure 2).

Second, InsP₃ is phosphorylated by Ins1,4,5P₃ 3-kinase to form Ins1,3,4,5P₄. There are three isoforms of this enzyme (InsP₃ 3-kinase A, B, and C). Both types A and B are activated by Ca²⁺/calmodulin, with the type B being the most sensitive. Ins1,3,4,5P₄ can either be dephosphorylated to inositol or can be phosphorylated further to generate an assortment of inositol phosphates, such as IP₆, IP₇, and IP₈, that may have additional signaling functions.

InsP₃ and Ca²⁺ signaling
